WE are pleased to recognize in this manual another evidence of the tendency to abandon the use of a course in qualitative analysis for practical instruction for beginners in chemistry. Dr. Long rightly observes that the system gives a distorted view of the relative importance of that department of chemistry. The complex problems set for the student in the usual qualitative course are not representative of the actual work either of research or commercial analysis. The classification by means of the so-called "group-reagents" is not a scientific one, but a purely arbitrary arrangement for a narrow practical purpose.

In the present work Dr. Long devotes over 250 pages to the experimental part; that is, detailed directions for performing 226 experiments, exhibiting the properties of elements and important compounds, and the general principles of chemistry. There are but twenty-two illustrations in this part, and most of these are not particularly commendable. We think it would be wise to illustrate such works quite freely, selecting the simplest apparatus, and to give a preliminary chapter of some length on the forms and uses of the standard articles, test-tubes, dishes, etc.

In the section on qualitative analysis the usual group-reagents are used. There are also chapters on spectroscopy, toxicology, and volumetric analysis. The decimal system of weights and measures is employed. The work is well printed.

CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, FROM FEBRUARY 7, 1896, TO FEBRUARY 22, 1896.

February 11.—STEELE, J. M., Surgeon, detached from the "Independence" and ordered to the "Monadnock."

February 19.—WALES, P. S., Medical Director, placed on retired list from February 27th.

GUITERAS, D. M., Surgeon, detached from the "Montgomery" and granted six months' sick leave.

CURTIS, L. W., Passed Assistant Surgeon, detached from duty at Indian Head Proving Ground and ordered to the "Montgomery."

MORRIS, L., Assistant Surgeon, detached from the naval hospital at Philadelphia and ordered to the Indian Head Proving Ground.

February 21.—DICKINSON, DWIGHT, Medical Inspector, ordered as member of the Retiring Board, February 28th.

ORIGINAL ARTICLES.

OSTEOPLASTIC OPERATION FOR LOSS OF SUBSTANCE OF THE TIBIA. SKIAGRAPH SHOWING RESULT.

BY HOWARD LILIENTHAL, M.D.,
OF NEW YORK;
ASSISTANT SURGEON TO MOUNT SINAI HOSPITAL.

THE following case is deemed worthy of record, because it exemplifies a rather rare surgical operation, and also because the result, as shown by the skiagraph, is quite different from what might have been reasonably surmised from the history of the operation, from inspection after recovery, and even from the most careful palpation.

M. S., a boy nine years old, was run over by a horse-car, early in June, 1894, and sustained a compound comminuted fracture of the right tibia, with severe laceration of the soft parts. There had been a left coxitis resulting in ankylosis some years before, but otherwise the boy was healthy. Severe infection, with profuse suppuration, so menaced the life of the patient that a surgeon, who saw him a few days later, entertained the idea that amputation would be necessary. On June 8th, about six days after his injury, his parents brought him to Mount Sinai Hospital, where I at once proceeded to drain the wound by several ample incisions. The tibia had been split and comminuted throughout almost its whole shaft, but by some lucky chance the fibula was intact. Many little detached pieces of perfectly dead bone were removed, and it was found that from two to two and a half inches of the lower third of the tibia was gone. The destruction of tissue had been so great that daylight could be seen through the leg for a space fully as large as a half-dollar. Recovery from this operation was slow but uninterrupted. Several pieces of dead bone were removed at various times, but finally every sinus closed. The limb was, however, useless without the aid of splint and crutch, the loss of tibial substance allowing the foot to flap about in rotation around the unbroken fibula. An aluminum splint was now ordered, and the boy was allowed to walk about with the aid of crutches in the hope that ossification of the interposed fibrous tissue might take place. I did not see the patient again for several months, and it was then noted that the head of the fibula had been apparently pushed away from its attachment to the tibia and projected well above the knee-joint, causing a deforming protuberance.

On July 23, 1895, fully ten months after recovery from the previous operation, I again operated to try to restore the function of the limb by

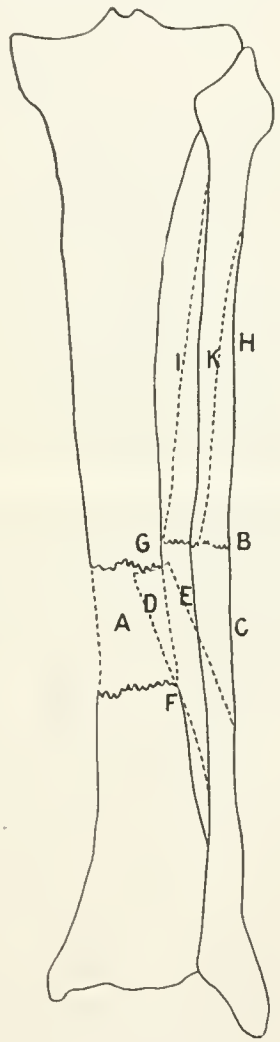

DIAGRAM OF OSTEOPLASTY.

tibio-fibular osteoplasty, an operation suggested by success in similar cases in the hands of Gerster, Sands, and others. A longitudinal incision was made over the hiatus in the tibia, *A* (see diagram), all non-osseous tissue between the two ends of bone was removed with the knife, the

bone itself being freshened with the chisel. A long incision was now made over the fibula and an osteotomy was performed, cutting the fibula at a point, *B*, just above the lower extremity of the upper tibial fragment. The lower fibular fragment, *C*, was now tilted inward in such a manner that its side rested against the lower piece of tibia, and its end rested against the end of the upper tibial fragment, as is shown by the dotted lines *D* and *E*. At *F* and *G*, holes were drilled through fibula and tibia and the bones were fastened together with thick twisted silk. The upper piece of fibula was held by the bandage so that it slanted toward the tibia in a position something like that shown by the dotted lines *I* and *K*, but it was not sutured. The skin wounds were now entirely closed with catgut stitches, and a firm dressing with a plaster of paris splint was applied over all and was kept in place for three weeks, when, at the first dressing, all was found to be healed, excepting two small sinuses, through which, later, the silk sutures and a small, loose piece of bone were removed. Bony union was very slow, and it was not until November, 1895, that I felt safe in allowing the splint to be discarded. Since that time the patient has been perfectly well and walks with only a very slight limp, which is due to his ankylosed left hip. The head of the fibula has returned to its normal position.

The skiagraph, which accompanies this paper, was very kindly made for me by a gentleman who modestly, but firmly, refuses to allow me to refer to him by name. The picture, though taken through the stocking and at a distance of fifteen inches from the source of energy, has been in its lower part somewhat overexposed. The view is a posterior one, which accounts for the seemingly reversed relations of the bones. It will be seen at a glance that the result is an almost normal position of tibia and fibula, with a very thick and dense bridge of bone connecting them obliquely. A faint light streak in the lower part of this bridge seems to indicate the medullary canal of the displaced fibula, but the free end of the upper fibular fragment has separated from the tibia and has assumed its normal position, being connected with the lower fragment of fibula by this same bony bridge. How this state of affairs was brought about, only a series of skiagraphs, taken at different times during the healing process, might have disclosed. It is, however, probable that if the light streak referred to is in reality the marrow canal of the fibula, that the upper fibular fragment assumed its nor-

mal position before the ossification of the callus. The new bone is evidently denser and stronger than the normal, which accounts for the perfect functional result. The boy was presented at the meeting of the Surgical Society of March 25th.

THE CLINICAL ASPECT OF CHRONIC DIFFUSE NEPHRITIS.[1]

By J. C. BIERWIRTH, M.D.,
of Brooklyn, N. Y.

My observations during the past ten years have impressed me with the idea that chronic diffuse nephritis is among the most frequent, if not *the* most frequent, disease in persons past middle life. This thought has grown stronger with every year, and often I have been appalled by the large number of cases seen in one year. There is also probably no disease which presents so varied a clinical picture, frequently made up of a series of vague and indefinite symptoms, difficult to diagnose, and hence often misinterpreted. In presenting this subject I desire to make a plea for an early diagnosis and the adoption of proper means for the comfort of the patient, and to guard him from the dangers, both immediate and remote, which appertain to this disease.

To my mind the classification of renal diseases made by Delafield[2] is the simplest and clearest. He divides them into acute and chronic parenchymatous, acute and chronic interstitial, and acute and chronic diffuse nephritis, and adds "that this classification seems to me to be theoretically correct, but yet I must admit that from a clinical standpoint nearly all the cases may be conveniently arranged into the two classes of acute and chronic Bright's disease." Under parenchymatous nephritis he includes all kidneys in which the lesion is confined to the epithelial cells lining the tubules and the capsules of the glomeruli; under interstitial nephritis, all those kidneys in which the lesion is in the stroma, and under diffuse nephritis, all those kidneys in which the lesion is in the tubes glomeruli, stroma, and arteries.

Chronic diffuse nephritis is more frequent in males than in females, and occurs chiefly in persons past middle life. Constitutional syphilis, intemperance, and privation, are counted among the most prolific causes. My personal experience has led me to think that the disease is especially frequent among brain-workers, among men whose nervous systems are continually on an overstrain, who have large business responsibilities, and who, as a rule, lead temperate lives. Whether their continuous strain leads first to changes in the arteries, owing to a faulty innervation and nutrition, and through these to changes in the kidneys, I am not able to state, but I incline to this belief. Chronic diffuse nephritis also occurs frequently in the course of all chronic diseases, such as phthisis, cirrhosis of the liver, emphysema, chronic suppurative processes in the bones or any part of the body, and especially in chronic gout and rheumatism.

As already stated, there is no disease which has so varied a train of symptoms. This will not seem strange when we consider that the symptoms are not dependent on the kidney lesions alone, but on the associate lesions as well. Of these, the changes in the heart and circulation have a far-reaching influence, and may produce symptoms in other organs, of such intensity as to mask entirely the original disease. The degree of the various lesions also modifies and changes the clinical picture, often to such an extent that we are for a long time in doubt as to diagnosis. The changes in the kidneys often escape notice of the patient entirely and he usually does not seek advice until circulatory disturbances make their appearance. Life insurance examinations discover many unsuspected cases. Disturbances of vision lead many to consult an oculist to whom changes in the retinal vessels and fundus reveal the first suspicion of the real malady, and of which the subsequent analysis of the urine is usually confirmatory. In some cases these retinal changes are the first symptoms, even before the urine gives any evidence of kidney disease, and these cases, I think, belong to the class where arterial changes are the cause of the nephritis. It would be impossible to enumerate all the different ways in which the disease may first show itself, but the chief interest is centered, no doubt, in an early diagnosis, for it is only in the beginning of the disease that treatment and advice may be of any benefit to our patients. They usually consult us about disturbances in any one of the organs of the body except the kidneys. Upon questioning them we find that they feel tired, suffer easily from headache, have occasional nausea and vomiting, have lost flesh and strength, and are not able to do their work properly. Upon examination we find them more or less anemic and listless, with an accelerated pulse, often an increased arterial tension and some hypertrophy of the left ventricle. There is usually present a slight degree of edema of the lower extremities, not sufficient to be noticed by the patient, but easily found when sought for by pressure over the

[1] Read before the Kings County Medical Association, February 11, 1896.

[2] The same author's description of these lesions is accepted.

tibia. This is perhaps the most common type of a beginning diffuse nephritis. These cases are often mistreated until an examination of the urine discloses their true nature. Others again complain of more or less severe neuralgic pains in different parts of the body, which do not yield to the usual remedies. These cases are rather of common occurrence, and I look with especial suspicion upon those complaining of severe attacks of sciatica. The pain may be due to a gouty or rheumatic diathesis, but in four cases seen during the last two years chronic Bright's disease existed.

One of these cases, a man, about fifty years of age, came to me suffering severely from sciatic pain. He was rather pale, pulse ninety and higher upon slight exertion, disturbances of digestion and some headache. He had slight edema over the tibia but had not noticed it, and did not think there was any change in the urine. The record of the urinary analysis showed: quantity, 38 oz.; sp. gr., 1016; albumin a trace; urea, 8 grs. per oz., or 304 grs. per 24 h., a few hyaline casts. The patient improved under treatment, but had a second and more severe attack of sciatica the following year, and died early this winter from an acute exacerbation of his chronic Bright's.

The other three cases have had several attacks, usually one each winter, but they are in good and fair health after the pain has subsided.

Another form in which this disease first shows itself is by a chronic cough, due to edema of the lungs. A case in illustration is the following:

A woman, about 60 years of age, consulted me in December, 1891, for a persistent and distressing cough, which she had had every winter for a number of years. She had been attended by three or four different physicians, each of whom had prescribed a cough mixture, with usually little or no benefit. An examination of her chest showed two or three patches of edema over the right lung, without any further lesion in the parenchyma or bronchi. Her temperature was normal, pulse rapid with moderate increase in tension and cardiac dilatation with some hypertrophy. The analysis of her urine showed decided evidence of renal changes. In the past five years she has had several acute exacerbations, from one of which I did not think she would recover. In the last attack she had general anasarca with much diminished urine and marked disturbance of heart and circulation. She recovered, however, and has been in very fair health during the past two years.

Repeated conjunctival hemorrhages have led me to discover renal disturbances of a grave character in cases where no other symptoms were present. There are other examples in which this disease comes to the surface, in the form of pains in the muscles of the extremities or trunk, analogous to rheumatism, but which are really due to excrementitious matters circulating in the blood, and not eliminated by the diseased kidneys.

The majority of cases of chronic diffuse nephritis under proper care and surroundings will go on for a number of years without getting much worse, but they are continually liable to acute exacerbations, one of which may end fatally, even though the pre-existing chronic disease has not advanced far. Cases are very apt to die if they are attacked by any severe illness, especially pneumonia. Individuals may have atrophied kidneys for years without presenting any symptoms, a suddenly fatal attack of uremia, brought on by exposure to cold and wet. The first evidence of the disease in others will be a sudden and severe attack of dyspnea, usually at night. While others again are attacked by pleurisy or pneumonia, or sustain some severe injury, when the inflammation of the kidneys will suddenly show itself.

The urine in chronic diffuse nephritis presents certain well-marked changes, although very variable in character. The amount in twenty-four hours is increased, in diabetes mellitus, diabetes insipidus, and in chronic Bright's disease, and it is diminished in all acute forms of renal disease, and in all diseases accompanied by high fever. In chronic diffuse nephritis we find the action of the kidneys by no means uniform, and we cannot lay down any law for our guidance. In my experience, I have found the quantity of urine but little altered from the normal, in quite a large percentage of cases it is rather diminished, to forty or thirty-five ounces, but in an equally large percentage of cases it will be found to be increased to sixty or seventy ounces, or to be normal. I believe, however, that in the course of every case of chronic diffuse nephritis, the amount is diminished at various times, and certainly always toward the end of the disease.

The specific gravity, however, falls regularly below the normal and, as a rule, varies between 1010 and 1016. Even if the quantity of urine is lessened, the specific gravity does not correspondingly increase. In some cases in which the quantity is increased to seventy ounces or more, it will fall to 1008 or 1005.

Albumin is present in nearly all cases, but usually only in small amount, the majority of cases showing a trace. If the urine shows a large quantity of albumin, the case is one of acute or chronic parenchymatous nephritis, or an acute exacerbation of a chronic diffuse nephritis. In

some cases, for a longer or shorter period, albumin may be absent; these, I think, are cases in which the kidney lesions are not far advanced and in which the albumin is the result of temporary circulatory disturbances.

Casts are to be found in nearly all cases, but in some they too may be absent for a varying period of time. Hyaline casts, of a very delicate structure and often difficult of detection, are chiefly found, although granular casts and an occasional epithelial cast may make their appearance from time to time.

The quantity of urea is regularly diminished in chronic Bright's disease. Allowing for considerable normal variations, physiologists state the amount in health to be about 500 grains in the twenty-four hours. In cases of chronic diffuse nephritis which have come under my notice, the amount has rarely been more than 350 grains, and as a rule, 300 grains or less. The other solids, phosphates, urates, chlorides, and sulphates, are usually diminished.

As the disease progresses we find a greater uniformity of symptoms. Owing to the faulty elimination of urea the celebral symptoms, such as headache, vertigo, convulsions, or coma, make their appearance and become more frequent. The gastric disturbances are more severe and persistant, vomiting being of frequent occurrence, edema of the feet and legs becomes more marked, and is noticed by the patients, and toward the end it usually goes on to general anasarca. Attacks of edema of the lungs are of frequent occurrence. Dyspnea is now a more constant symptom, at first only upon going upstairs, then upon slight exertion, and finally it becomes continuous. The pulse becomes more accelerated, is irregular and intermittent, and the arterial tension is high. In some cases the patients die from an attack of uremia, in others from the general anasarca and exhaustion, an attack of pneumonia, or an effusion into the lateral ventricles of the brain. An acute exacerbation may prove fatal at any time in a patient in whom the chronic diffuse nephritis had previously produced but little disturbance, and these acute exacerbations are the source of greatest danger to the patients suffering from the disease.

Having obtained one of the above-enumerated histories, our diagnosis naturally depends upon an analysis of the urine, and it is owing to the lack of proper care and precaution in this that so many cases escape detection. It should be made the rule that only a specimen of the entire twenty-four hours secretion be examined. If we take a specimen from any part of the twenty-four hours, and do not find it to contain albumin, we can never positively assert that the kidneys are not diseased. Furthermore, we must bear in mind that one analysis is not conclusive, for albumin and casts may be absent for quite awhile, and, if we do not find them at first, one or two analyses per month, made during a period of six months, will usually clear up the case. It is also necessary to know the exact quantity secreted during the twenty-four hours, so as to be able to determine the total amount of urea and other salts. The search for albumin is usually our first step in the analysis, and owing to the fact that in chronic Bright's disease it is usually present in only very small amounts, a trace, its detection is often difficult, and unless great care be exercised, it is not found. The urine to be examined should first of all be perfectly clear, as otherwise a slight turbidity cannot be detected. Fresh urine can be rendered clear by one or two filtrations through a double wet filter. If not successful the addition of a small portion of caustic potash will precipitate the earthly phosphates, which carry down the remaining impurities. Should the specimen continue cloudy after filtering out the earthly phosphates, the addition of a few drops of the magnesia mixture will cause a copious precipitate of the alkaline phosphates, leaving the urine perfectly clear after filtration. The tests employed for the detection of albumin are so numerous that it is impossible to treat of all of them here. Every one who is in the habit of making frequent analyses of urine accustoms himself to one or two tests and disregards the rest. I have used and tried most of them, but of late have confined myself to two: the heat and nitric acid and the ferro-cyanide of potassium tests. In searching for albumin, we must bear in mind that all urines contain more or less mucin, or, as it should be more properly called, nucleo-albumin, which is precipitated by most of the tests used in testing for albumin, including the heat and nitric acid test. The only test which does not precipitate mucin is the ferro-cyanic test. Purdy, in his recent work on "Practical Urinalysis," mentions a test with a saturated solution of chloride of sodium and acetic acid, which is said not to precipitate mucin. I am not familiar with it, but it is easily applied and might be used as an extra test in doubtful cases. My procedure in testing for albumin is usually as follows: Starting with a perfectly clear acid urine, I fill a test tube to the depth of 1½ inches with it, boil it, and add 10 to 15 drops of strong nitric acid,

cork up the test tube and set it aside for 6 to 12 hours. It is necessary to set the tube aside for some time, as in traces of albumin a precipitate often does not make its appearance until 15 or 20 minutes after boiling. The next day the precipitate will have settled at the bottom of the test-tube, leaving the urine clear above. I then boil the specimen a second time, and, if I find that the precipitate does not re-dissolve, I conclude it is albumin.

I believe that if the nitric acid be added in sufficient excess, the mucin present will be held in solution and not interfere with the test unless it be present in considerable amount. Next I test the urine with a five per cent. solution of ferro-cyanide of potassium. I can best explain the application of the test by quoting from Purdy's work on "Practical Urinalysis": "Into the bottom of a clean test-tube is poured 15 to 30 drops of acetic acid; then about two or three times that amount of solution of potassium ferro-cyanide ($\frac{1}{20}$) is added, and the two thoroughly mingled by shaking the tube. The urine is next added, to the depth of two-thirds of the test-tube. If albumin be present, it will be precipitated throughout the whole volume of the urine in the form of a more or less milk-like flocculent cloud, according to the albumin present. The ferro-cyanic test applied by the above method avoids the mucin reaction, and precipitates all varieties of albumin, acid and alkaline. On the other hand, it gives no reaction with phosphates, urates, peptones, the vegetable alkaloids, or the pine acids." When these two tests are carried out faithfully as directed, I do not think any trace of albumin will escape detection. I was much gratified to see in a recent paper by E. E. Smith, Ph.D.—"Notes on Urine Analysis"—read before the Section on General Medicine of the New York Academy of Medicine, December 17, 1895, and published in the New York *Medical Record*, January 4, 1896, that he strongly advocates the above-recited two tests for albumin. He adds, however, for the detection of mucin a comparison tube, "an inch of clarified urine is placed in a test-tube, and two drops of dilute acetic acid are added." If a turbidity results in this tube, and a precipitate results from the heat and ferro-cyanide tests, then he ascribes the latter to mucin and not albumin. My experience thus far does not agree with this view; I have not had time to test it sufficiently, but my impression is that the ferro-cyanide test, as given by Purdy, does not precipitate mucin.

The next substance to be tested for is urea, *i.e.*, to determine the quantity excreted in the twenty-four hours; but I will not occupy your time in describing the mode of making these tests. Excretion of urea in twenty-four hours, in a case of chronic diffuse nephritis, is rarely above 300 grains, but how low the amount may fall without producing cerebral symptoms, is difficult to determine. The tolerance of urea in the blood varies markedly in different persons; some give uremic symptoms when they pass 200 grains or over, while others are perfectly comfortable when excreting only 75 to 100 grains. I am inclined to think that there are other factors besides urea or its derivatives which aid in the production of uremia. The urine of every patient suffering from chronic Bright's disease should be frequently examined for urea, and a daily test should be made when cerebral symptoms are present; for upon the amount of urea, and not upon the amount of urine excreted, depends our treatment and prognosis. We test for albumin and search for casts to make our diagnosis, but when these are once found and the presence of the disease is established, we need not recur to them again, for neither the number and kind of casts nor the quantity of albumin determine the prognosis and influence the treatment, but urea will, throughout the continuance of the case, require our constant attention.

The prognosis of chronic diffuse nephritis is always grave; the cases all end in death sooner or later, but many live for a long time in comparative comfort if properly cared for.

I do not believe that anything can be done to retard the progress of this disease, or remove the existing changes in the kidneys. Such drugs as bichloride of mercury, chloride of gold, arsenic, iodide of potassium, etc., have in my judgment no curative influence on the kidneys. If they do good, they do so by acting as general tonics, by improving the appetite and the condition of the blood. In the beginning of the disease all our efforts should be directed toward improving the general condition of the patients, in the hope that thereby we may retard the progress of the disease. They should live in a climate where this danger is reduced to a minimum, and that is a warm climate, where an out-of-door life is possible. If their means do not permit this change of climate, they should remain indoors during the winter months and live in as equable a temperature as possible. As a rule, they should give up their business pursuits, and live a life of ease and comfort, avoiding all excitement. All vicious habits should be given up, and the use of

alcohol, except perhaps a glass of wine as an appetizer, should be prohibited. The skin should be kept in as active a state as possible, by frequent baths. The diet should be nutritious and easily digestible, and in patients who suffer much from gastric disturbances, it should consist largely of milk. I am in the habit of letting them take but one solid meal per day, the other two meals being composed entirely of milk. Unless valvular disease is a complication, it has seemed to me that the circulatory disturbances are caused chiefly by an obstructed flow of the blood, due to the increase in arterial tension, and, no doubt also, to the obstruction in the renal circulation. The indication for the treatment of these symptoms then naturally suggests such remedies as nitrite of amyl, nitro-glycerin, and iodide of potassium. The first is rarely indicated except during an attack of uremic coma, or convulsions with high tension and a bounding pulse. Nitro-glycerin is certainly one of the most valuable remedies which we possess in this disease. Some patients have to take it more or less all the time. I usually give it in tablet form, $\frac{1}{100}$ of a grain every two, three, or four hours. If the tension is great it may be given every fifteen minutes until the pulse becomes soft, and then the interval may be lengthened to one or two hours. Iodide of potassium is certainly the best drug in this disease; it fulfills all the requirements by producing a dilation of all the arteries and maintaining it, and producing little or no disturbance if given in some bitter infusion, sufficiently diluted, and only after meals. My patients usually take it for two to three months at a time, in doses from fifteen to twenty-five grains daily. If the heart's action is too rapid, aconite in small doses is a valuable remedy, and if a cardiac stimulant is needed I prefer the fl. ext. of convallaria in ten to fifteen-drop doses, three or four times daily. Digitalis is in my experience objectionable, because of its great tendency to derange the stomach, and to increase arterial tension. Strophanthus is valuable, and iron and oxygen are excellent as general tonics. During an acute exacerbation the patient should be put to bed and kept on an exclusively milk diet, with applications of dry-cups over the kidneys, followed by hot fomentations. When the disease is far enough advanced to produce uremic symptoms, such as headache, twitching of the muscles, convulsions, coma, the more active measures, such as sweating and purging should be employed. Opium is, I think, a valuable remedy, although a dangerous one, in these conditions.

PHARYNGO-MYCOSIS LEPTOTHRICA.[1]

By JAMES T. CAMPBELL, M.D., M.R.C.S.,
of Chicago.

Almost all the cavities and the tubes of the body, which communicate with the exterior (*e.g.* alimentary tract, vagina, urethra, etc.), contain bacteria in abundance, even under normal conditions. The mouth is the natural habitat of many pathogenic and non-pathogenic organisms. Ordinarily the pathogenic organisms do no harm, sometimes however, they are capable of giving rise to disease. Thus, while the majority of us carry about with us constantly in our mouths the micrococcus lanceolatus, comparatively few individuals develop a croupous pneumonia. To the group of harmless organisms in the mouth belongs the ordinary leptothrix buccalis; it is almost constantly present, even in health, on the gums and between the teeth, and the finding of it, as a rule, would therefore be of no particular interest.

But, under certain circumstances, this organism can give rise to peculiar phenomena in the pharynx and grow in the form of characteristic colonies. The condition of the pharynx was named by B. Fraënkel,[2] in 1873, pharyngo-mycosis leptothrica. Jacobson[3] suggested that the name be changed to algosis faucium leptothrica, since it is now known that the leptothrix must be classed among the algæ and not among the fungi. Subsequent writers, however, have retained the older nomenclature.

The disease affects the following parts in order of frequency: the tonsils, the base of the tongue, the glosso-epiglottic fossettes, the posterior and lateral walls of the pharynx, the faucial pillars, the naso-pharyngeal vault, the upper part of the esophagus and the nasal fossa. Ackermann[4] has recently reviewed the whole subject in an address before a medical society in Griefswald, and describes at length the clinical and pathological phenomena met with in the disease. The colonies present a white or yellowish-white appearance, and form soft or horny polypoid masses or flat excrescences. In the tonsils they occur most often in the crypts. According to Heryng, the spreading may occur in two ways: (1) Through the formation of superficial excrescences upon the mucous membrane, which appear more or less bulging and firmly adherent. (2) Through the formation of wedge-like triangular processes

[1] Read before the Chicago Medical Society, December 2, 1895.

[4] *Deut. Med. Woch.*, 1894, No. 46.

which break through the epithelium, and may extend deep into the parenchyma of the tonsil. As a rule, both tonsils are affected. At the base of the tongue the circumvallate papillæ and crypts are frequently affected. In many cases the disease is associated with an unusual amount of mental depression, which increases the deterioration of the general health; in others the subjective symptoms are but slight. The disease is usually discovered accidentally.

The symptoms complained of by the patient generally consist of a slight tickling, dryness, or burning in the throat; there may be slight dysphagia and sometimes a slight cough. Rarely there may be fever or anorexia.

As regards the etiology, little is definitely known. It was formerly thought to be secondary to caries of the teeth. Miller states, however, that the diseases of the teeth are due to other parasites, and that in them the leptothrix appears only secondarily. Adults are generally affected, females suffering more frequently than males.

Diagnosis.—When one has once seen a case the diagnosis can be made without the microscope. The condition must be distinguished from *lacunal tonsilitis*, a disease with an acute febrile onset, general constitutional symptoms, swelling and reddening, in which the flecks are soft and friable, readily separable, and easily raised with a probe; from *tonsillar concretions*, which can be easily enucleated, do not recur after removal and often disappear without treatment; from *herpes angina*, which invades the arch of the palate; from *diphtheria*, a disease in which there are severe general and local symptoms. The membrane is firmly adherent, requiring some force for removal, and then leaves a bleeding surface. Cultural methods establish the diagnosis; from *syphilitic plaques;* from *tuberculosis;* from *thrush* or *soor;* from *pemphigus.*

Course.—Generally very obstinate. The plugs artificially removed often return; occasionally there is a spontaneous cure. All agree that antiseptic solutions and astringents are insufficient. The best results are obtained by removal with forceps and cauterization.

The following case illustrates well the main characteristics of the disease:

Miss M., aged eighteen years; consulted me on September 16, 1894. In December, 1890, she suffered from a severe attack of diphtheria which seemed to have left the throat hypersensitive, since slight exposure invariably resulted in "sore throat," with accompanying white patches on the tonsils. These spots or patches, together with the soreness, usually disappeared in the course of three or four days under the employment of simple gargles. At no time had the spots remained longer than one week. These attacks came on at all seasons of the year, but more frequently during the colder months. In November, 1893, she contracted scarlet fever, and had again a very sore throat. Attacks of "sore throat" reappeared at intervals of about two months up till August, 1894, at which time, after the repeated employment of the usual gargles, it was observed that, though the soreness had passed away, the white spots remained. These have been present constantly till September, 1894, at which time I first saw the patient and made the following note: Over the whole surface of both tonsils and a small part of the adjacent post-pharyngeal wall are yellowish-white dots, corresponding in the main to the crypts normally found in these regions. The pillars of the fauces and tongue are quite free. The dots vary in size and shape, being rounded like millet seeds, mushroom and spur-like; some projecting out from the lacunæ for a distance of from 4 to 5 mm. These plugs look as if they could be easily brushed away, but when seized with the forceps are found to be adherent and very tenacious, so much so that the whole tonsil is drawn forward, and often there is a little bleeding after removal. There is no surrounding inflammatory areola. There are no carious teeth. The patient says that the throat seems dry, and the sensation is as if a foreign body, such as a bristle from a tooth brush or a fish bone, had lodged upon the tonsils. The tongue is clean, the breath not offensive. She complains of some slight physical and mental depression. About one month after first coming under observation a few spots developed on the right side of the base of the tongue adjacent to the tonsil. During the course of the disease there was noticed some apparent fusing of spots to form a small membrane not unlike diphtheritic patches.

A portion of the left tonsil was abscised and sent for examination to Dr. Lewellyn F. Barker, assistant resident pathologist to the Johns Hopkins Hospital, Baltimore, who reports as follows:

"The pieces were fixed in two ways: one set in absolute alcohol, another in sublimate. The alcohol tissues were imbedded in celloidin; the sublimate tissues in paraffin. Sections were stained in hematoxylin and eosin, in safranin, in Lugol's solution, and by Gram's method.

"A few patches are seen upon the surface of the mucous membrane, but in the main the disease process is confined to the crypts, which are filled with fine plugs visible to the naked eye. On microscopical examination these plugs are seen to consist of a central core of horny squamous epithelium, clinging to which are masses of bacteria and bunches of the characteristic leptothrix threads. Shreds of epithelium project laterally from the main core, and between these micro-organisms are abundant.

"The leptothrix masses consist of bundles of threads more or less parallel to one another, which run usually almost at right angles to the central core of epithelium. In some sections, however, long wavy bundles are seen running parallel to the long axis of the crypt. These masses are easily visible in sections stained in hematoxylin

and eosin, but are best differentiated in those stained with Lugol's solution and mounted in glycerin. The iodin stains the starch granules in the threads a deep bluish-black color, and the masses are readily distinguishable from the tissue, or from any other micro-organisms which may be present. In addition to the leptothrix there are masses of bacteria of various kinds, mainly short, rather delicate bacilli, along with clumps of flat epithelial cells and small mononuclear cells situated between the plug and the wall of the crypt. The epithelial lining of the crypt is rather thicker than normal. There is no excess of lymphoid cells in the epithelial wall, though these cells are abundant in the crypts, forming in places masses of considerable size between the plug and the wall of the crypt. In some cases the epithelial core of the plug is directly continuous at the bottom of the crypt with the epithelium of the mucous membrane.

"The patches on the surface of the mucous membrane of the tonsils consist also of flat plates of horny epithelium, to which are attached masses of leptothrix and bacteria. These epithelial plates are separated in places from the surface of the mucosa and in the interspaces, in addition to the masses of the alga, are seen loose, flat epithelial cells, lymphoid cells, an occasional leucocyte with polymorphous nucleus, and aggregations of bacteria. There are no marked alterations in the sub-epithelial tissues, or in the follicles of the tonsils. The *Keimcentra* show numerous mitoses, but apparently not more than are normally present in well-fixed tissues. The curious groups of distorted nuclei noticed at the periphery of some of the sections, and at certain spots in the interior, are probably to be attributed to the action of the alcohol. The case is undoubtedly one of the so-called pharyngo-mycosis leptothrica of B. Fraënkel (Aigosis faucium leptothrica of Jacobson)."

Treatment.—Tonic doses of iron, quinin and strychnin were ordered, and after the individual plugs were pulled out, chromic acid, fused on a fine probe, was applied to the interior of each crypt. The actual cautery was tried but found less satisfactory than the chromic acid. Four months after the commencement of treatment all evidence of the disease had disappeared. Various other methods of treatment have been advised. The consensus of opinion gives to the galvanocautery the first place. Ruault advises smoking ten cigarettes daily. Baber[1] recommends the local application of alcohol. Nitrate of silver and a whole host of antiseptics have been employed.

Inasmuch as it has been stated that an acid medium is favorable to the development of the spores, Hemenway[2] suggests that the use of the positive galvanic pole with a large negative cutaneous electrode should be more effective than cauterization.

Since this paper was written, pharyngo-mycosis has appeared on the tonsils of an adult sister of the patient, whose case is herein described, which would indicate the possible contagiousness of the disease.

CLINICAL LECTURE.

GASTRITIS GLANDULARIS CHRONICA.[1]

By PROF. FENTON B. TURCK, M.D.,
of the University of Chicago.

Gentlemen: In a previous lecture I called your attention to the principal etiological factors of chronic inflammation of the stomach, which are errors of living, diseases of other organs, and neuroses. To these must be added, as potent factors of inflammation, certain saprophytic germs and their toxins, the effects of which will be considered in the present lecture.

When any or all of the factors that I have enumerated have caused an irritation of the mucous membrane, exudation follows, and a sticky material accumulates upon the stomach wall. This material is made up of thick, tenacious, glue-like mucus, in which are found gland cells, leucocytes, food detritus, or remnants of food that are partly digested. The lack of churning power helps to cause retention of food particles. The material alluded to adheres to the gastric mucosa as a sticky mass. It is the best culture medium for the various germs found in the stomach that I have yet been able to procure. In drop cultures, by using this material as the nutrient medium, the stomach bacteria show rapid multiplication. My study has been limited to the pathogenic germs. The special conditions favorable to their growth are food and protection, and they grow better in a constant temperature, such as is maintained in the stomach.

The peptones and albumoses of the stomach are also found in this mucous bed. The gland cells and other epithelial cells contain a rich protoplasm, which is the best class of food, or culture soil, for these stomach bacteria. I have utilized this fact in my method of growing germs upon the sterilized mucous membrane of the stomach of pigs.[2] The hydrochloric acid of the gastric juice does not markedly interfere with the development of bacteria in this mass. The acid at first is even increased, as the germs multiply, owing to the irritation of the toxins of the growing colonies upon the stomach wall. Mucin not being freely soluble in water, the H_2Cl and HO do not penetrate the mucus sufficiently to destroy the colonies growing in such a rich soil. In cases of this kind I found that the acidity of the mucus was very faint; in other cases the reaction was alkaline or neutral. In ordinary process of digestion the HCl is not secreted, as a rule, unless food is taken into the stomach, when it forms syntonin and other fixed chlorides, so that two or three hours after food has been taken HCl is not, as the rule, found in the stomach. In every case where germs have been introduced into dogs' stomachs, after methods which I have before explained and which I will soon show, I have found evidence of the increase of HCl in the presence of growing germs which were formed upon the stomach wall,

The method I have pursued for obtaining this material from the stomach wall for bacteriological investigation is

[1] Lecture delivered by invitation of the Faculty and Trustees of the Jefferson Medical College, Philadelphia, February 10, 1896.
[2] See *Wiener medicin. Wochenschrift*, Nos. 1 and 2, 1895.

by the gyromele, which I have described elsewhere.[1] After the material has been removed from the stomach by this instrument, slides are made and stained and cultures are made, growing the germs on the mucous membrane of the stomach of a pig (sterilized by fractional sterilization at 60° to prevent coagulation of albuminoids). Bouillon made from the chopped mucous membrane of the pigs stomach forms a rich medium for cultures. Other nutrient media employed are gelatine, agar-agar, and boiled potatoes. These methods have the advantage of furnishing the natural habitat of the stomach bacteria. Cultures can be forced on the mucous membrane of the stomach as it does not melt at the same time, the liquefying germs are shown by little areas, when they liquefy. Many forms grow that do not grow at all upon ordinary nutrient media, and others grow better than they would under other circumstances. Finally, the mucous membrane can be dried and the colonies transported, if desired.

In experiments upon dogs, tannic acid is used every day for two weeks as an etiological factor. This "knocks out" the stomach and makes it a suitable field for germ culture. Now, if we put in the material taken from the walls of the stomachs of patients suffering with gastritis, the germs will grow; the soil has been prepared and the infection is produced. The results observed in the mucous membrane are that the gland cells become cloudy, leucocytes come to the surface, and the pathological picture of inflammation produced is identical with that found in cases of gastritis in the human subject. Material taken from the surface of the mucous membrane is examined, and also bits snipped off by Turck's nippers, designed for this purpose. The small wound left after taking away a small piece of the mucous membrane with this instrument will heal in 24 to 48 hours, leaving no evidence of the lesion.

As the germs grow then certain changes are observed, which appear to be due to the effects of the toxins. In order to settle this positively and learn what effect toxins have, I sterilized them as follows: In the morning, before breakfast, I withdrew the contents of the stomach, filtered through a Pasteur filter, and made the fluid germ-free. When sterile, I injected the fluid in doses of 1, 2, 3, up to 10 cc. to each 1000 grams of the animal. Rabbits at first were used, but subsequently I found common house rats better for the purpose, because they are not so large, are cheap, and can be watched just as well. The separation of the albumoses and peptones from the toxic proteoses of bacterial origin cannot be accomplished practically by chemical means. I have, however, taken advantage of the fact that coagulation of various albumoses takes place at different degrees below the boiling point (100° C.). By producing a vacuum over the filtered fluid taken from the stomach a rapid evaporation takes place, and by heating to 60° C., to 80° C., to 90° C., and up to 100°, various albumoses have been taken out which show marked difference in their effects when injected into the animal.

The normal stomach, when compared with an infected stomach, especially in cases of gastritis with marked dilatation, shows a wide divergence in toxicity of the secretions. In some cases, in the latter condition, 5 cc. has killed 1000 grams of animal when injected. There is also a difference observed depending upon whether the stomach has been cleaned out the night before or not. If the stomach has been washed and no food given, and the gastric fluid withdrawn in the morning, the fluid obtained is not so toxic in effect as in other cases where this procedure has not been followed. The employment of starch food instead of meat also lessens the toxic effect. The explanation of the latter observation is that the germs may grow and furnish a more potent toxin in the presence of albumin than in the presence of starch, or that the albumoses and peptones are more toxic than starch products. When no food at all has been given for twenty-four hours, cases of gastritis show the toxic effect of the injured stomach fluid.

Pathology.—The study of the pathological effect has been upon an artificial gastritis produced in dogs. The stomach of the dog, as before stated, is first treated with daily doses of tannic acid for two weeks, which produces a mild catarrh. The pathological condition allows the thick mucus to adhere to the walls of the stomach, where cells and remnants of food accumulate and in an adherent mass that forms a culture medium for germs. If now the material taken from the stomachs of patients suffering with gastritis is daily introduced, the phenomena of inflammation are rapidly developed; the symptoms observed are an increase in the production of HCl, the ferments become more active and the food is more rapidly propelled into the intestines. By the use of the gyromele, material is now removed from the stomach wall and the material thus secured is subjected to examination. Microscopically, the slides show leucocytes, a few gland cells, and food detritus in a bed of mucus. I now show you one of the dogs, which I have brought with me in the first stages of gastritis. The condition may be studied through a permanent fistula, which I am in the habit of making in a peculiar manner. I make a valvular opening in the anterior wall of the stomach, by following the mucous membrane in such a way as to make a valve similar to the ileocæcal valve, so that when a speculum is introduced and a small electric lamp, the whole of the interior of the stomach can be inspected. No leakage takes place at other times, as the valvular fold of the anterior wall prevents the escape of the stomach contents. This I consider the most useful method of operating for gastric fistula. I have performed the operation twice in the human subject for carcinoma of the esophagus.

On examination of the dog's stomach in the first stage of artificial gastritis, the stomach shows, here and there, accumulations of mucus and other material upon its walls. At the points not covered there is hyperemia, as shown by a red coloration of the surface.

I have divided chronic inflammation of the stomach, or gastritis, into three stages for the sake of convenience. Many times the changes characterizing the three stages have been observed in the same animal; but it is better to have some system in describing the morbid appearances. In order to examine the mucous membrane microscopic-

[1] International Medical Congress at Rome, 1894. *Wiener Med. Woch.*, Nos. 1 and 2, 1895; *Journal of the American Medical Association*, March, 1895, and *New York Medical Journal*, October, 1895.

ally, to learn the pathogenic changes that take place, it was necessary to secure pieces of the affected mucous membrane from time to time and observe the progress in the inflammatory change. Formerly, I made several laparotomies on the same dog, taking a piece of mucous membrane each time for examination; but many errors crept in. I accordingly devised this instrument which I call "Nippers," which passes down into the stomach through a tube, and when it arrives in the stomach, the nippers or pincers are exposed and a small piece of the mucous membrane is snipped off. This is then submitted to microscopic examination. It is found that the first change to be observed in gastritis is that the gland cells are enlarged and appear cloudy, also numerous leucocytes are noticed at the surface. But the evidences of inflammation are not so marked in this stage as in subsequent examinations, where the progress is more advanced. A far better idea is gained in the macroscopical examination with the electric light. The points especially to be noted are the accumulated mucus on the walls with the marked appearance of hyperemia. In the control dog (normal), a hyperemia occurs on the introduction of anything like a tube, into the stomach; the normal slate color changing to a light pink, but in inflammation, the mucous membrane becomes a bright red color.

After three or four months of this experiment of introducing infective material into a dog's stomach, more marked changes are observed. Not in every dog experimented upon, but in sufficient number to make it evident, there is a decreased formation of the HCl after a period of increased production of HCl. The food remains longer in the stomach, the dog does not eat with the readiness observed in the first stage, when the HCl is increased and the ferments more active. The dog then begins to emaciate. This thin animal that I have brought here to-night, shows this marked disassimilation, yet he is supplied with all the food necessary at regular times. The pieces of mucous membrane removed show more advanced cellular changes. The cells of the glands are so indistinct that they simulate a thick lining membrane. When a piece is secured from the pyloric extremity of the stomach, which is done by pushing the instrument along the great curvature, no distinction can be made, as in the normal condition, between central and parietal cells. Many of the cells are exfoliated, some show a fatty condition, and the specimen I have here, shows mucoid change. This mucoid change may be accounted for by the fact that the peptogenic cell is exhausted and can no longer secrete pepsinogen; but, as irritation continues, it produces mucinogen instead. I know of nothing in pathology of the stomach that makes such a beautiful picture. The cells look like a string of beads lining the glandular tubules, and when projected by the stereopticon, they look like little oval windows, like opals. The cystic degeneration of some of the glands and the mucoid metamorphosis of others, may account for the diminished production of the HCl and ferments. As the process continues, round cells that at first only appeared here and there, now congregate and multiply. The leucocytes entirely coat the surface. Cells become loosened and fall off; round-cell infiltration takes place with the formation of connective tissue, even down through the mucous coat. This part of the inflammation is what is mostly observed *post-mortem* and in advanced cases of gastritis. The earlier changes that I have observed are entirely lost in the *post-mortem* changes. In order to study these early changes the pieces of mucous membrane must be examined at once after their removal from the living tissue. Formalin is the best to preserve and harden the specimens; glycerin and water is also of value, and may be used.

At times, in the examination of patients suffering with symptoms of gastritis, small fragments of mucous membrane will come out in the wash water. On making slides from these pieces much valuable pathological information is gained. Changes similar to those that I show you in these specimens, of gastritis artificially produced in dogs, may be seen, corresponding to the different cellular changes in the stages of inflammation. The cells of the glands and the leucocytes find their way to the surface and accumulate in the bed of mucus adhering to the stomach wall. When my gyromele is introduced into the stomach, this material is removed by the revolving sponge. When I find the evidences of inflammation so marked in the material thus obtained for examination, I make the diagnosis of gastritis whatever other conditions may be present. The special points noted microscopically are the leucocytes, the altered gland cells, and the colonies of bacteria imbedded in the mucous bed.

In the study of inflammation of the stomach in the embryo it seems that the entoderm is far more sensitive to irritation than the ectoderm.

Gastritis glandularis chronica is an inflammation that appears the same as inflammation of any other part of the body, the only differences being the location and the peculiar manner in which infection takes place. By the decomposition of food and the growth of micro-organisms in the stomach poisons are produced which may be absorbed and produce local irritation as a general toxic effect, but this is not inflammation nor the direct factor or cause of gastritis. All errors of living, errors of diet, decomposition of food, etc., may be and are powerful etiological factors in producing inflammation of the mucous membrane. Any agent that irritates or changes the mucous membrane, so that material adheres to the stomach wall and allows bacteriological growth to occur in this bed, is an etiological factor in gastritis. As the mucous cells and food detritus accumulate on the stomach wall, germs develop in colonies and form toxins which are freely discharged. Part of the toxins are taken up by the cells beneath, and two changes are observed at the beginning of the process: increase of functional activity and slight changes in the gland cells with migration of leucocytes. The increase of HCl and of the ferments, and increased muscular activity of the stomach are accompanied by hyperemia. The irritation being continued and constantly present; after a time there is exhaustion of the function, a decrease of HCl, or it is entirely absent; there is also diminished ferment production and muscular weakness. The organ becomes easily distensible and dilatation occurs. HCl

may yet be increased or diminished, but as the process progresses there is gradually loss of all function, and, if no stop or change is produced in its course, the inflammation goes on to atrophy and total loss of digestive power.

I have secured a great variety of stomach bacteria in my studies of cases of gastritis, and I can say that it is not the presence of two or three germs that decides inflammatory change, but the group of micro-organisms found in the stomach. When these groups of stomach bacteria, pathogenic or non-pathogenic, colonize in the rich soil found in the mucous layer adhering to the stomach wall, they form toxins, which produce both the functional changes and the pathological phenomena of inflammation. The ability to find these products on the walls with the gyromele has enabled me, by cultivation and experiment, to clear up a few of the mysteries of "Catarrh of the Stomach."

CLINICAL MEMORANDA.

THE CLINICAL STUDY OF FOUR CASES OF INSANITY TREATED WITH THYROID EXTRACT.[1]

By WILLIAM E. WRIGHT, M.D.,
OF HARRISBURG, PA.;
FIRST ASSISTANT PHYSICIAN, PENNSYLVANIA STATE LUNATIC HOSPITAL.

REPORTS upon the therapeutic value of the thyroid gland in the treatment of certain forms of nervous affections have recently been so favorable that one feels that he would be doing himself and his patients an injustice if he did not give the drug a fair trial, and draw his own conclusions as to its value. The beneficial effects of its action in some cases of myxedema can hardly be disputed. Perhaps the flattering results of its action in this affection has entitled the drug to the position it now holds as a therapeutic agent with the dermatologist, as well as the neurologist and alienist.

The theories of the function of the thyroid gland[2] are reported by Victor Horsley as follows:

First.—That it is for the purpose of preserving the contour of the neck.

Second.—That it acts as a mechanical cushion to protect the important vessels and nerves from compression effects exerted by the contracting muscles.

Third.—That it acts mechanically to support the larynx and improve the voice.

Fourth.—That it acts mechanically, and protectively causes anemia of the brain.

Fifth.—That it acts mechanically, and protectively prevents anemia of the brain.

Sixth.—That it manufactures some substance specially necessary to the integrity and proper functional activity of the central nervous system.

Seventh.—That it is directly a blood-forming organ.

Eighth.—That it is indirectly a blood-forming organ.

Ninth.—That it plays an important part in the metabolism of the sex-organs.

Tenth.—That it modifies or destroys substances which, circulating in the blood, are harmful to the general economy.

From this list of its functions it would seem that the gland plays a more important part in the human economy than has heretofore been accredited to it by physiologists. The drug has been given a trial by many hospital physicians, both in this country and abroad, but to Dr. Louis C. Bruce, Assistant Physician, Royal Asylum, Edinburgh, is due special praise for his careful observations and report of "Thyroid Feeding in Insanity."[1]

It was my good fortune to be serving as clinical assistant on the staff of Royal Asylum, Edinburgh, at the time of some of his experiments with the drug, consequently I was afforded the opportunity of carefully observing the effects of it and noting the results upon the mental affection. Dr. Bruce reports the following cases with the following results, viz:

Three Cases of Acute Mania, All recovered.

Four Cases of Acute Melancholia, Two recovered, one relieved, and one not improved.

Three Chronic Cases, Mania drifting into dementia, of over one year's duration. One male relieved.

Two Cases of Chr. Melancholia, One female of over four year's duration, discharged relieved. One female of over two year's duration, discharged recovered.

One Case of Syphilitic Insanity, Not improved.

One Case of Alcoholic Amnesia, Not improved.

Four Cases of Puerperal Insanity, Three recovered after one course of treatment. The fourth recovered after the second course of treatment.

Two Cases of Lactational Insanity, One of over five month's duration, recovered. The other of over two year's duration, not improved.

Three Cases of Climacteric Insanity, All recovered.

Two Cases of General Paresis, One temporarily improved, the other relieved.

This is certainly a most brilliant showing and justifies a trial of the drug by every one who has to treat the insane.

Dr. Bruce's cases encouraged me so much that I was full of hope, and I came home with the determination of giving my patients the benefit of the experiment.

Four cases were selected. Cases of tardy convalescence inclined to pass into a state of dementia. Two were over one year's duration, and two were under six month's.

The patients were weighed and put to bed, their temperature and pulse rate were observed morning and evening. No restriction in diet was made. About the fourth day after being in bed a five-grain tablet of thyroid extract was given. The second day two tablets were given, and the third day three, and so on until patient received three tablets or fifteen grains of the drug three times daily. Not until this dose was reached was there a noticeable reaction. It is well here to note that the temperatures of patients had been running 97° to 98° before the drug was given, and pulse was not above seventy-five in any case, and in one was as low as fifty per minute. At this dose there was a slight feverish reaction. Temperature running from 90° to 100° at times.

[1] Read before the Harrisburg Academy of Medicine, February 28th.

[2] *British Med. Jour.*, January 30, 1895.

[1] See *Journal Mental Science*, January, 1895.

The most noticeable effect was observed in the pulse rate, which was quickened, sometimes irregular and generally without tone. This was considered the key to the full physiological effects of the drug, and when the pulse became atonic and irregular the drug was discontinued. In each case the drug was administered about six or seven days after the dose of fifteen grains three times daily had been reached. At this point the drug was discontinued though patients were still kept in bed, as at this stage the treatment had produced rather an exhausted state and the danger of heart failure was to be considered. As soon as it was prudent (generally the fourth or fifth day) the patients were permitted to get up, were again weighed and permitted to mingle with the other patients on the hall. No other medicine had been given during the treatment with the thyroid, save mild laxatives in one case. After the drug was discontinued, patients were all given tonic treatment in some form, with egg-nogs and other extra articles of diet, with the view of stimulating the appetite and increasing the nutrition.

Case I.—W. M., male, age 61. Melancholy, with suicidal tendency. Takes food very reluctantly, and is very emaciated. Weight 120 pounds. Temperature 97°. Pulse 50. Treatment outlined above was carried out, the extract being administered for nine days, and ten weeks later it was noted that, with the exception that patient takes his food better, there is no noticeable change produced in his condition by the action of the thyroid. Weighs 120 pounds.

Case II.—M. G., male, age 30. Hereditary predisposition. Melancholia of one year's duration. Is suspicious, and practices masturbation. Very thin; weighs only 115 pounds. Takes food reluctantly. Temperature 98°. Pulse 60. The thyroid extract was taken for sixteen days by this patient, and ten weeks later the following note was entered: Takes his food better. Weighs 112 pounds. The increase in appetite is the improvement to be noted in his case. Mentally there is hardly any change.

Case III.—G. D., male, age 21. Hereditary predisposition. Case of mania. Restless, disorderly, quarrelsome, and practices masturbation. Weighs 137 pounds. Temperature 98°. Pulse 70. Patient was sent to bed and the thyroid extract given for eight days in all, but very little reaction was observed. Ten weeks later the patient is more orderly and less destructive. Is less quarrelsome, and keeps himself in better shape than he did. Weighs 136 pounds. His condition can be classed as improved.

Case IV.—M. Z., male, age 22. Hereditary history on both sides. History claims that he had been maniacal and destructive at his home, though patient was in a stupid state and refused food when he was received into the hospital. For two days he refused food, and was fed with a nasal tube. Later he is recorded as being dull and stupid, and growing more demented. Patient is sent to bed. Pulse 70. Temperature 97°. Weight 135 pounds. Extract administered for thirteen days, and ten weeks later patient was very much brighter. More tidy in habits, and helping to do ward work. Decided improvement.

While the results of the experiment are not so favorable as I had wished for, still I think that all of the patients are in a way better for having received the drug. Increased appetite and power of assimilating food is certainly marked, and this, in a certain class of cases, is a gain. This, however, may be due to the after-treatment with tonics, stimulants, and extra articles of diet; but this treatment, given before the administration of thyroid, did not produce the increase which is to be found after the latter drug is given.

As the result of my observations, I give the following summary:

1. That the drug produced a decided reaction in all the cases, as is shown by the feverish state and quickened pulse.

2. That the patients lost in weight and became quite feeble during its administration.

3. That the patients developed an increased desire for food, and gained in weight as soon as the drug was discontinued.

4. That the effect upon the mental state is so slight as to hardly justify the period of time and inconvenience to patient of confinement to bed and the risk incurred by the administration of the drug.

ACETANILIDE AS AN ANTISEPTIC IN CHRONIC SUPPURATIVE OTITIS.

By LEWIS S. SOMERS, M.D.,
of Philadelphia.

Acetanilide, phenylacetamide, or, as it is commonly called, antifebrine, has been used for a number of past years as an antipyretic and analgesic. In 1893 Harrell[1] called attention to its use in suppurating wounds, and reported a number of cases in which it was used with excellent results. Later, Morton[2] reported one thousand miscellaneous surgical cases in which it was substituted for iodoform and found superior to the last-named drug. Morton mentions one case of head injury, with aural hemorrhage, in which he packed the external canal with the pure drug. Allen[3] relates one case of chronic suppurative otitis treated with acetanilide, cure resulting in a very short time. Referring to the *Surgeon-General's Catalogue* and the *Index Medicus* for references relating to the use of acetanilide in chronic suppurative otitis media, I find the drug, as used for that purpose, conspicuous by its absence, no reference being given to any article on the subject. I therefore feel justified in recording the cases and results of its use as embodied in this preliminary report.

Believing thoroughly that a suppurative ear should be treated on the general lines of antisepsis and asepsis, as taught by our modern medicine, it seems a logical conclusion that moisture (*i.e.*, permanent instillations of liquids into the canal and middle ear) should be avoided, not only that fluids macerate the delicate structure with which they come in contact for varying periods of time, but also form a nidus favorable to bacterial growths, thus setting up secondary infection in an ear already the seat of a morbid process.

[1] Harrell, Medical News, Vol. 63.
[2] Morton, *Trans. Phila. County Medical Society*, 1894.
[3] Allen, *Cotex Medicus*, Vol. I.

Based on these principles, it is therefore a desideratum to find a suitable dry application that will protect the inner ear, render it aseptic, will not irritate, and, finally, not form hard, insoluble masses or be absorbed by the system, with deleterious results. In the small number of cases reported in this paper, acetanilide apparently fulfils the objects desired. It is neutral in reaction, odorless (this one point alone renders it far superior to iodoform), non-irritating, to a greater or less extent soluble in the purulent discharge, and does not form lumps or cake. To a moderate degree antiseptic, and acting as it does, by clinging to the mucous membrane, thereby forming a coating, preventing extraneous germs from gaining access to the ear. When used as a pure powder, without dilution, it sometimes causes slight pain and a stinging sensation, and to obviate this a powder is best made of equal parts of acetanilide and boric acid, which does not produce pain and causes no abnormal aural sensation. Another factor, although a minor one, which is not without value, especially in hospital use, is the low price of the drug, and, as very little is used on an individual case, the per capita cost is reduced to a fraction of a cent.

Acetanilide is but one part of the treatment of suppurating middle ear disease; important, but to insure success, a number of additional points in the treatment must be strictly adhered to. The routine treatment used on the cases reported in this paper was a follows: The aural canal and middle ear were thoroughly cleansed of pus and debris (as epithelial cells, extraneous matter, and cerumen) with a fifteen-volume solution of hydrogen peroxide, the pus in the canal being easily removed with a tuft of cotton on an applicator. Frequently, to remove the products of suppuration from the middle ear, a delicate syringe was used, and all parts of the ear covered with the discharge were rendered as antiseptic as possible. Necrosed bone being removed with forceps and curette, and polypi or granulation tissue thoroughly removed with the snare, nitrate of silver or chromic acid. Bleeding being controlled with alcohol, the acetanilide powder was then blown into the canal so as to cover its entire floor with a fine film, extending on the membrana tympani to the lower portion of the perforation. A very important point in the use of any powder in the ear is to use but a minimum quantity and to avoid obstructing the opening in the drum, as it is nature's method of evacuating the pus. Very frequently, if this point is neglected, the products of suppuration will be unable to escape externally and, as the Eustachian tube is often glued together by inflammatory products, the pus, endeavoring to discharge in the direction of least resistance, will invade the mastoid cells and set up a mastoiditis. As the streptococcus and staphylococcus readily find entrance through the Eustachian tube and infect the middle ear, particular attention should be paid to the nose and naso-pharynx. Every case, therefore, was thoroughly cleansed with an alkaline antiseptic solution, a modification of "Seiler's solution" being found most agreeable. All abnormal changes in both throat and nose were removed and, as far as possible in such exposed organs, antisepsis was maintained. This treatment, being based on common-sense principles, cannot fail to produce good results, as it always has in my hands, both with and without the use of acetanilide.

The patient is instructed to avoid self-treatment of the ear, and especially not to use a syringe or insert a cotton plug, as is very frequently the case, always with deleterious results in a large majority of instances. In cases with the disease of long standing and a profuse mucopurulent discharge, instructions are given to clean the external ear with castile soap and warm water, using for that purpose a clean piece of linen, and immediately destroying it, thus never using the same piece of infected material over again. Previous to the use of acetanilide as a dusting powder, the routine method of treatment as above outlined was always used, with the exception that an impalpable boric acid powder was used in its place. But results were frequently disappointing, the suppuration continuing to exist in spite of all endeavors to effect a cessation.

The cases treated by this method are reported somewhat in detail, so that the extent of the otitis and the results obtained by the use of acetanilide may be better appreciated:

Case I.—A. N., age 10 years. Admitted to the clinic of the Union Mission Hospital December 26, 1893. Right ear has been suppurating for several years. Tympanic membrane entirely absent. Regular treatment of no avail for one year previous. Otitis cured in three months with acetanilide. No return at present time.

Case II.—C. S., age 14 years. Admitted April 14, 1895. Both ears suppurating. Total cessation of discharge in three months.

Case III.—S. C., age 46 years. Admitted May 23, 1895. Left ear suppurating and tympanic membrane destroyed. Cured in five weeks.

Case IV.—W. D., age 11 years. Admitted April 16, 1895. Both ears suppurating irregularly for the past ten years. Both membrana tympani absent. Cured in ten weeks.

Case V.—C. S., age 24 years. Admitted May 7, 1895. Suppuration on right side. Perforation embracing lower segment of membrana tympani. Cured in three visits.

Case VI.—I. L., age 3 years. Admitted May 13, 1895. Right ear suppurating for past three months, caused by scarlet fever. Cured in two visits.

Case VII.—M. L., age 5 years. Admitted May 15, 1895. Sister of Case VI. Left ear suppurating for past three months, following scarlet fever. Cured in five visits.

Case VIII.—M. McE., age 2 years. Admitted May 16, 1895. Right ear suppurating since he was nine months old. Cured in one application.

Case IX.—W. F., age 39 years. Admitted September 10, 1895. Left ear suppurating for past two weeks. Drumhead entirely absent, except Shrapnell's membrane. Cured in three visits.

Case X.—P. F., age 9 months. Admitted May 25, 1895. Left ear suppurating. Cured in three weeks. Previous to this he suffered from a mastoid abscess on the left side, which was operated on by Dr. Isaac Leopold.

Case XI.—J. K., age 15 years. Admitted May 25, 1895. Left ear suppurating. Cured in four weeks.

Case XII.—K. B., age 17 years. Admitted June 1, 1895. Both ears suppurating. Cured in six weeks.

Case XIII.—T. T., age 31 years. Admitted June 1, 1895. Left ear suppurating for past twenty years. Cured in eight weeks.

Case XIV.—G. L., age 16 years. Admitted August 16, 1895. Left ear suppurating for past year. Membrana tympani shows double perforation in posterior inferior quadrant. Cicatrix on right membrane from previous myringitis. Cured in three weeks.

Case XV.—I. T., age 14 years. Admitted August 24, 1895. Both ears suppurating since early childhood. Left membrana tympani absent, except a portion of Shrapnell's membrane. Right side shows total absence of drumhead; both oval and round windows easily distinguished. Cured in one week.

Case XVI.—A. W., age 7 years. Admitted August 3, 1895. Left ear suppurating, discharge commencing soon after birth. Small perforation of drumhead below umbo. Cured in four weeks.

Case XVII.—H. S., age 30 years. Admitted October 20, 1895. Intermittent suppuration of left ear since early childhood. Entire posterior segment of drumhead destroyed. Cured in one application.

Case XVIII.—J. S., age 6 years. Admitted August 1, 1895. Left ear constantly suppurating for the past three months; previous history of irregular discharge. Entire membrana tympani absent. Cured in three months, with formation of new membrane.

Case XIX.—C. R., age 11 years. Admitted October 1, 1895. Left ear suppurating for several years. External auditory canal filled with bleeding granulations. After these were removed the tympanic membrane showed a large perforation embracing its posterior half. Cured in seven weeks, with formation of new membrane.

Case XX.—L. W., age 8 years. Admitted October 12, 1895. Both ears have been suppurating for the past year. Left tympanic membrane shows lenticular perforation of Shrapnell's. Right shows a large inferior perforation, involving lower two-thirds of drum. Cured in one week, with formation of new membrane.

Case XXI.—C. R., age 16 years. Admitted September 2, 1895. Left ear suppurating for one month. Tympanic membrane swollen and edematous in superior half. Medium-sized perforation of lower posterior quadrant. Cured in three weeks.

Case XXII.—J. B., age 39 years. Admitted October 10, 1895. Right ear has been suppurating for the past three days. Septic dermatitis of external auditory canal and catarrhal inflammation of Eustachian tube. Small perforation over attachment of manubrium to membrane. From the amount of destruction present, the disease had very probably existed for several years, but owing to the ignorance of the patient, a definite history was not obtainable. Cured in one month.

Case XXIII.—K. S., age 21 years. Admitted September 21, 1895. Pus has discharged from the left ear irregularly for the past five years. Absence of membrana tympani. Large bunch of granulations occupying location of posterior inferior segment of drum. Cured in two months.

Case XXIV.—F. G., age 9 years. Admitted November 30, 1895. Intermittent purulent discharge from right ear for several years. Large circular perforation of anterior inferior quadrant of membrane. Cured in three weeks.

Case XXV.—W. F., age 10 years. Admitted December 10, 1895. Pain in right ear one week ago, followed by a purulent discharge. No previous trouble with ears. Membrana tympani boggy and congested, with a small perforation of the anterior inferior quadrant. Cured in one visit.

Case XXVI.—M. K., age 28 years. Admitted November 13, 1895. Intermittent suppuration of both ears for the past five years. The left membrane shows a large central perforation, almost involving the entire drumhead, with congestion of Shrapnell's membrane. Right side shows a small annular perforation of anterior inferior quadrant. Cured in three weeks.

Next to acetanilide, boric acid is undoubtedly of more value than any powder now used in chronic suppurative otitis media. With the last-named drug, and without detailing cases from clinical reports and my own experience, it has usually taken on an average of thirty applications to the ear to cure the diseased process. The word cure is used advisedly, as in a certain number of cases suppuration will occur at irregular intervals, usually from tubal infection, due to coryza and pharyngitis, and in the class of patients seen in hospitals from unhygienic surroundings and lack of care of the ears, especially in children among the poor.

In the series of cases reported above, an average of twelve treatments was sufficient to remove all evidence of discharge, thus making a very material decrease in the treatment rate. Applications were made three times a week, so the average course of treatment extended over one month, instead of from three to five, as is usually the case when treated with other applications. The longest treatment extended over a period of three months, while in several cases one application was sufficient to produce a satisfactory result. From the history of the duration of the disease, it was found that the longest period of existence was twenty years, while the shortest was but three days' duration, giving an average duration of very nearly three years. The average age of the case at beginning of treatment was 16½ years, the youngest being 9 months and the eldest 46 years.

MEDICAL PROGRESS.

Intra-uterine Transmission of Vaccinal Immunity.—At a recent meeting of the Académie de Médecine Ausset (*Bull. de l'Acad. de Méd.*, 1896. No. 3. p. 51) communicated a report of the case of a man, 27 years old, who had been vaccinated several times without success—once during infancy and twice at the age of 20 years. The fourth attempt, at the age of 27, was followed by the development of characteristic lesions. It appeared upon in-

quiry that the individual's mother had suffered from an attack of variola during the pregnancy (the exact period could not be ascertained) but the patient presented no lesion of the disease. It seemed, therefore, probable that his resistance to vaccination was due to the protective influence of substances that passed from the mother to the fetus through the placenta.

Prolapse of the Uterus and Vagina in a Nullipara.—CHOLMOGROFF (*Wratch*, 1895, No. 49, p. 1370) has reported the case of a woman, thirty years old, who had never been pregnant, but who presented complete prolapse of the uterus of three years' duration. Menstruation appeared first at the age of sixteen, and had always been regular, but painful. The uterus was entirely external to the vulva, was increased in size, and was easily replaced. The external orifice was open and surrounded by a suppurating erosion. Cystocele and rectocele existed. Urination was easy and painless. On auscultation, râles were heard at the apices of the chest; expectoration was abundant, and consisted of mucus sometimes sanguinolent. Sweats occurred at night, and cough was obstinate, especially in the morning. After reduction of the uterus a glycerin tampon was introduced, and renewed hourly for six hours. After a time a long and broad strip of the vaginal wall was removed, and the cut edges approximated by sutures. A month later hysteropexy was practiced, and the result was entirely satisfactory. The woman, however, returned to her work, which consisted in lifting heavy weights, the pulmonary symptoms became more aggravated, and in the course of six months the prolapse had returned.—*Presse Médicale*, 1896, No. 13, p. 78.

Bilateral Ovarian Cystomata in Three Sisters.—As a contribution to the subject of the hereditary transmission of ovarian cystomata, LOHLEIN (*Monatschrift für Geburtshülfe und Gynækologie*, 1896, B. III, H. 2, p. 91) reports the cases of three sisters, all of whom presented cysts of both ovaries, which were removed by operation. Olshausen, who has probably enjoyed the largest experience of similar nature, has reported the cases of three sets each of two sisters, in which he has operated for the removal of ovarian cysts upon one side.

Osteoplastic Restoration of the Metatarsus.—CRAMER (*Centralblatt für Chirurgie*, 1896, No. 5, p. 99) describes a mode of operative procedure adopted by Prof. Bardenheuer in the restoration of a defect caused by the removal of the third metatarsal bone on account of disease. After removal of the diseased structure the adjacent second metatarsal bone is divided longitudinally by means of a chisel, but not through its tarsal extremity, whose relation with the middle cuneiform bone is preserved. The inner half of the divided bone is then deflected into the place of the removed third metatarsal bone, and to its distal extremity the first phalanx of the third toe is attached. The operation has been successfully performed in a case of tuberculous caries in a boy six years old. The joint between the tarsus and the metatarsus was not opened. The interval between the second and the fourth metatarsal and between the two parts of the second were packed with gauze. At the end of four weeks the child was dismissed and given permission to stand on the foot and to walk after two weeks more. Five months after the operation the boy was able to move the affected foot freely, and the member was well-formed and like its fellow. The operation is similar to that which has already been employed in the correction of congenital defect of one of the bones of the forearm or leg, and is applicable to other conditions of an analogous character.

Successful Treatment of Dracunculus Medinensis by Injection of Mercuric Chloride.—MANSON and BOYD (*British Journal of Dermatology*, 1896, No. 2, p. 38) have reported the case of a Lascar, forty-two years old, who presented a projection from a small sinus just above the left external malleolus, which was found to consist of some two inches of guinea-worm, and which was wound upon a stick. The protruding piece of worm was cut off, and the fluid contained in the proximal extremity examined, without, however, finding living embryos. This extremity became retracted within the sinus and could not be drawn out. The trickling of cold water over the leg from a sponge failed to cause exudation of embryo-laden fluid, and it was therefore concluded that the worm was empty. After three days of simple dressing without result, an Esmarch bandage was applied as a tourniquet above the malleoli, and an incision an inch long made over an elongated low swelling, about 1½ inches in extent, situated two inches above the mouth of the sinus. At once an opaque white cord about one-sixteenth inch in diameter, was seen at the upperend of the wound. This was pulled out with a hook, and presently the dried end of the worm appeared. By careful traction, about four inches of the length of the parasite was thus withdrawn. This portion was a thin-walled, but strong, empty tube. Into the buried portion of the worm was injected 1–1000 solution of mercuric chloride, but this penetrated only a short distance. Some of the solution was also injected into the tissues about the mouth of the sinus. The worm was cut off as high as possible, and the wound closed. In eight days the wound had healed entirely, without general or local reaction.

Hemiparesis and Gangrene of the Forearm in the Sequence of Extirpation of the Uterus.—At a recent meeting of the Royal Society of Physicians of Vienna BRAUN (*Wiener klinische Wochenschrift*, 1896, No. 5, p. 74) related the case of a woman, sixty years old, in which immediately after vaginal extirpation of a carcinomatous uterus, there were noticed paresis and a livid discoloration of the right hand and forearm, and of the right lower extremity. The operation had been performed with the patient in the usual position, and examination of the heart had disclosed no lesion. In the course of a few days the arm became livid, and pulsation could not be felt in the corresponding axillary and brachial arteries. The bodily temperature fell below normal. The vascular conditions in the lower extremity gradually improved, while those in the upper grew progressively worse. Amputation of this member was deferred until some indication of the limits of the gangrene should manifest itself. Paresis also ap-

peared on left side of the face, and the palsy of the lower extremity became complete. On several occasions a fatal issue threatened, but each time the patient rallied. Power gradually returned in the palsied members and a line of demarcation formed in the right forearm, so that at the end of three months amputation was performed without anesthesia and without pain.

In the discussion Weichselbaum, to whom the amputated member was referred, stated that the probable explanation of the course of events depended upon the detachment of calcareous fragments from the walls of the atheromatous vessels and their lodgment in the left sylvian artery and in the arteries of the right arm.

Cerebral Traumatism and Dipsomania.—At a recent meeting of the Medico-Legal Society of Paris Vallon (*Presse Médicale*, 1896, No. 13) reported the case of an officer in good health and of good habits and good family history, who was thrown from his horse, one foot being caught in its stirrup, and dragged for a considerable distance, his head striking the ground. The man suffered an extensive wound of the nucha and was unconscious for three days. At the end of three months he returned to his regiment in apparently good health, complaining only of ringing in the ears. Subsequently he had an attack of uncertain nature in which he fell and lost consciousness. It was now noticed that the man displayed an entire change of habits, indulging in alcohol to intoxication and suffering from a veritable mania of thirst; he was besides erotic and manifested a tendency to suicide. This condition continued, the man going from bad to worse.

A New Method of Treating Wounds Antiseptically.—Schleich (*Therapeutische Monatshefte*, 1896, No. 2, p. 57) has found that when a watery solution of gelatin is evaporated over formalin-vapor a new product results, which is hard, transparent, and resistant to ordinary influences, such as heat, moisture, alkalies, and acids, and which is chemically inactive. Experiment showed that when this formalin-gelatin was introduced into the peritoneal cavity of animals it was in part digested and surrounded by new-formed connective tissue. The introduction into wounds of pathogenic bacteria, together with powdered formalin-gelatin was unattended with infection, thus proving that the formalin set free exerted an antiseptic influence *in loco*. The observations were extended to human beings, with the invariable avoidance of suppuration, except in the presence of necrotic tissue (as from ulceration) and of specific infections (such as tuberculosis or syphilis). When from the presence of necrotic tissue, deposits or secretion, healthy cells were prevented from coming into contact with the formalin-gelatin and setting free formalin, this was effected by means of a solution of pepsin (5 parts) in hydrochloric acid (0.3 part) and distilled water (100 parts). Formalin-gelatin is prepared by the addition to 500 grams of purified gelatin in solution 25 drops of pure formalin solution and evaporating over formalin-vapor. The resulting solid body is reduced to powder and preserved in the presence of a drop of formalin solution. Impregnated with lime-salts, formalin-gelatin is capable of taking the place of defects in bone.

THERAPEUTIC NOTES.

The Treatment of Tetany with Thyroid Extract.—Levy-Dorn (*Therapeutische Monatshefte*, 1896, No. 2, p. 63) reports a case of idiopathic tetany of three years' duration in a woman 21 years old, which, after resisting varied treatment, yielded upon the administration, over a period of nearly four weeks, of four grains of thyroid extract at intervals of one, two, or three days.

Styptic in is a yellowish, bitter powder, readily soluble in water, the results of whose employment in gynecological practice Gaertig details in the *Therapeutische Monatshefte*, 1896, No. 2, p. 71. The drug chemically resembles hydrastinin, and is the chloride of cotarnin—a base obtained by the oxidation of narcotin. It was at first used in powder-form in cachets, later in a solution of which 10 drops represented gr. ¾, and finally in the form of perles. At first gr. ¾ were given twice daily, subsequently the same dose four times daily, and finally increased to eight times in the twenty-four hours. No influence upon uterine contractions was observed, so that any hemostatic action possessed by the drug is attributable to some other cause. The medicament was employed in cases of uterine hemorrhage of varied origin and proved serviceable in the larger number, equalling in efficiency hydrastinin, than which it is cheaper.

The Treatment of Scarlatina with Anti-Streptococcous Serum.—Marmorek (*Annales de l'Institut Pasteur*, 1896, No. 1, p. 1) details the results achieved in the treatment with anti-streptococcous serum, of ninety-six cases of scarlatina at the Hôpital Trousseau from October 16 to December 31, 1895. Seven additional cases coming under observation during this time were not treated with the serum because of the lateness of the disease. One of these presented a nephritis of three weeks' standing and remained under observation for two months without progressing to recovery. Two sisters of this child, who were attacked later, were treated with serum and recovered without complication. In all of the ninety-six cases streptococci were found, alone or in association with other micro-organisms. In seventeen cases diphtheria-bacilli were present. Four of these presented symptoms of diphtheric intoxication and died, notwithstanding treatment with both the anti-streptococcous and the anti-diphtheric serum. These children had been several days without treatment. One other child died as a result of bilateral pneumonia. All of the children received at first a dose of 10 c. cm. of the serum. The dose was doubled if the general condition appeared grave. In addition only antiseptic lavage of the throat was employed. The injections were repeated daily until the temperature became normal. Ordinarily two injections proved sufficient. When complications, such as adenitis, otitis or albuminuria appeared, the injections were resumed, and continued until the normal condition was restored. No bad effects were observed from the use of the serum. It influenced only the complications due to streptococci.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

SATURDAY, APRIL 4, 1896.

THE PLAYFAIR INCIDENT, AND THE SACREDNESS OF PROFESSIONAL CONFIDENCES.

NOTHING has happened in recent years to direct attention so sharply to the responsibility of the physician, in his confidential relation to his patients, as the verdict of $60,000, in an English court, against Dr. Playfair, the celebrated obstetrician, of London. The circumstances, as reported in the daily press, are that Dr. Playfair was called in consultation by the family physician of a lady who was ill. This lady's husband had been in Australia for about one year. Whatever the condition was, Dr. Playfair was led to believe that the lady had not been a faithful wife. She, being his own wife's sister-in-law, he accused her of infidelity, and reported the matter to his wife, warning her that the patient was not a proper person for her to associate with.

This led to the lady being cut off from her annual allowance from her father-in-law of $2500 and to her practical ostracism from society. Then she sent for her husband, who staunchly believed in her honor and brought the suit which resulted in the vindication of her character and the recovery of damages for defamation of character to the amount of $60,000.

If the reports, as given in the daily press, are true, Dr. Playfair must look in vain for sympathy from his professional brethren. If the doctor's only intent was to protect his wife and family, he could have done it in some way without betraying his patient's confidence.

The physician stands in honor in exactly the same relation to his patients as the priest to those who confess to him. The priest receives and encourages this confidence on the mutual belief that it is for the confessor's spiritual good. The physician does the same on the mutual belief that it is for the confessor's physical good. One is as sacred as the other. The doctor learns his patient's ailment simply that he may treat it; but the remote influences of the moral and spiritual life of his patient has so great influence on the physical that it becomes sometimes necessary to make his confessional as far-reaching as that of the priest, and it, therefore, behooves the doctor to guard with zealous care not only the knowledge he may thus gain, but the very suspicion that he has it. On this point the Code of Ethics of the American Medical Association speaks with no uncertain sound. Section 2 of Article I says:

> The familiar and confidential intercourse, to which physicians are admitted in their professional visits, should be used with discretion and with most scrupulous regard to fidelity and honor. The obligation of secrecy extends beyond the period of professional services; none of the privacies of personal and domestic life, no infirmity of disposition or flaw of character observed during professional attendance should ever be divulged by the physician. The force and necessity of this obligation are indeed so great that professional men have, under certain circumstances, been protected in their observance of secrecy by courts of justice.

In the account of the trial it is reported that Sir John Williams, physician to the royal family, declared that it was within the discretion of any of the 23,000 physicians in England, on his own responsibility, to disclose a secret without consulting the patient, if he deemed it his duty for the protection of his wife or family or in the case of a crime. This moved the Judge to inquire if he considered it the duty of a physician to inform the public prosecutor in case he found that a patient had submitted to an illegal operation.

Sir John replied that the College of Physicians had answered "Yes" to precisely that question. But Justice Hawkins tartly observed that if every medical man in the kingdom testified that he had a right to betray a confidence under certain circumstances it would not alter the law or his responsibility under the law.

A doctor is not a moral censor; nor can he consider it his duty to punish, by exposure and defamation, sins which he may have discovered in his professional confidences.

What view the law takes of this subject, in various parts of our country, is as difficult to ascertain as to know what regulations the different States have for the practice of midwifery and which are devoid of any. Doubtless the law here regarding the communication between physician and patient is about the same as it is in England. In New York State the Code of Civil Procedure declares:

A person duly authorized to practice physic or surgery shall not be allowed to disclose any information which he acquired in attending a patient in a professional capacity and which was necessary to enable him to act in that capacity.

In view of the outcome of Dr. Flayfair's experience, it may be well to remember that if a doctor reveals a professionally gained secret he does so at his peril.

THE MORAL ASPECT OF THE TENEMENT-HOUSE QUESTION.

A good deal has appeared lately in lay and medical periodicals upon the subject of the tenement house and the "rear" tenement house in particular. It is known by most readers that, in the thickly crowded districts of all large cities, in what should be the back yard of the house that fronts the street, another house is erected, connected with the street only by a narrow, covered passageway leading through the front house. This is the "rear tenement" about which we hear so much and which is credited with being the hiding and breeding place of so much disease, vice, and crime. No thinking person can for one moment deny that the *proper housing* of an urban population is for them the most important problem. If overcrowding simply meant disease and death to a large percentage of those overcrowded, the reformer might simply deplore the loss of life in a philosophical way. But disease and death are trifles compared with other dangers from which thoughtful persons recoil with horror. We refer here to the moral side of the question.

The home is the bulwark of our civilization, but the word "home" is not in the vocabulary of the tenement house, and, as eight-fifteenths of our city population so live, they know not the meaning of the word. Defined by a rat, home means one thing; by a civilized human being it means something more—an abode furnishing the comforts of domestic life. These comforts are sunlight, an abundance of uncontaminated air, a sanitary water-closet, a bath-tub, and enough rooms to secure privacy. An abode not having these modest amenities of civilization is not a home, be it a squalid rear tenement or a "flat." In the poor tenement sunlight is almost unknown; the air is only a fraction of the legal 600 cubic feet per tenant, and is contaminated by foul odors and deadly emanations.

The New York Tenement-house Committee reported in 1894 that in one block of 2,000 tenants there was not a single bath-tub, and the secretary of that committee reports that of a population of 255,033 inspected, only 306 persons had access to bath-rooms in the houses in which they lived.

But, as here contended, lack of sunshine, air and cleanliness, and consequent disease and death, count as naught. The moral is the greatest danger, and the lack of privacy is the most damnable feature of the tenement. In the better class of tenements there is a front or sitting-room, having perhaps two narrow windows looking on the street, a back room, generally used as a kitchen, with a window or two, and between the two rooms are two more, unlighted and unventilated except through the front and back rooms, serving both as bedrooms and as a passage-way from kitchen to sitting-room. In these rooms a father and mother and several children, perhaps grown, cook, eat, dress and undress, bathe, sleep, live in health and sickness, and die. Under the most favorable circumstances such a life is not conducive to modesty, and if purity and morality survive it is a marvel. Shift the scenery a little and in the same rooms imagine a drunken father or mother, or both, children of an impressionable age, and perhaps a boarder or two to take a hand

in the frequent brawls or debauchery, and the vision of the tenement house as a nursery for future citizens begins to take shape. But instead of four rooms, suppose there is one, partly below ground, dark, damp and noisome, and suppose this the only abode of a family or of several adults of both sexes, with children, and you have a true picture of how many city dwellers live. An abode where marital acts or promiscuous relations of the sexes are open, where drunkenness, lewdness, and crime go hand in hand, presents a problem that should be met and solved.

It is futile to appeal to the humanity of the landlord, for he is the exception who voluntarily tears down a rickety house yielding twenty-five per cent. and puts up a sanitary tenement yielding ten per cent. It is useless to look for reform to the tenants themselves, stolid and morally benumbed as they are. As long as unfit habitations exist they will find tenants, and there is only one way to solve the problem and that is to invest the Board of Health with powers of expropriation.

When a tenement cannot be made a sanitary habitation or where a landlord refuses or neglects to make it so, the city should step in, pay the owner what the building is worth for old material, tear it down and leave, at least, a breathing space where before was a hotbed of physical and moral infection. If there ever was an excuse for the State to exercise its power of eminent domain, it is where its poor stand in need of light and air, which should be free to all; where vice and crime flourish because virtue and honesty are impossible; where the very existence of the State is threatened because a large part of its younger citizens, if they escape disease, fall victims to a social rot.

OPHTHALMOLOGY.

A CRITICAL RESUME OF RECENT PROGRESS.

Herbert Burnham, M.D. (*Arch. of Ophthal.*, Vol. XXIV, No. 3, p. 407), reports the use of pilocarpin in connection with the iodide of potash and mercury, in the treatment of an obstinate case of syphilitic iritis, in which the prolonged use of atropin, mercury, and the iodide of potash had been of little avail. The sulphate of pilocarpin was used hypodermically in the dose of $\frac{1}{8}$ grain once a day, and gradually increased to $\frac{1}{4}$ of a grain. The injections were given daily for three weeks, when not contra-indicated by excessive nausea or by weak heart action.

An interval of two or three weeks was then allowed to pass, and the treatment repeated. The mercury and potassium were continued without intermission. Under the treatment the inflammatory condition gradually subsided, the synechiæ disappeared almost entirely, and the otherwise intractable diseased condition passed on to recovery.

Dr. Burnham intimates that as the addition of pilocarpin to the mercury and potassium, in the treatment of this case of syphilitic manifestation, proved so valuable, it may also be of similar value in the treatment of obstinate syphilitic affections of other parts of the body. The establishment of the free action of the mucous membranes, the glands of the skin and of the salivary glands must certainly aid in the elimination of the toxic principle of syphilis, as well as of other diseases, from the system.

The question of the presence of glands in the ciliary body, as advocated by E. Trecher Collins, (Vol. XI, *Trans. Ophth. Society of the United Kingdom*) has been again taken up by Alt (*Amer. Jour. of Ophth.*, Vol. XIII, No. 1). These small diverticula in the pigment layer of the ciliary body, which are most marked in the vicinity of the union of the pars ciliaris nonplicata with the pars ciliaris plicata, can be seen in any anteroposterior section of this part of the human eye, but are rendered more easily visible by bleaching sections after Collins' method. Alt formerly regarded these follicular depressions as being due to folds produced by the play of the ciliary muscle, but since he has found them partly developed in the eye of the fetus, he is inclined to believe that they are not due to this cause. The pigment layer of the greater portion of the ciliary body, like that of the iris, represents two layers of the posterior portion of the secondary eye vesicle, which has become folded upon itself during the process of the development of the eye, and the character of the cells in the depressions mentioned do not differ from those found in the pig-

mented layer spread out over the ciliary processes and other portions of the surface of the ciliary body. The vascularity in the part mentioned is not as great as we would expect to find in active gland structure and cannot compare with the vascularity of the ciliary processes or of the iris. Since the function of secretion is undoubtedly possessed by the pigment cells of the pigment layer of the retina, it is not unreasonable to attribute such function to the pigment cells of iris and ciliary body, and if this is the case we must adopt the view of Nicati, that the ciliary body and iris form one large gland from which is derived the secretions to the interior of the eye.

In the operative treatment of detachment of the retina, American and English surgeons have occupied conservative ground, but few of the various methods that have been advanced having originated with them. German and French ophthalmologists have introduced new methods of treatment from time to time, and have claimed for them results that were very gratifying. Incision of the sclerotic and choroid, beneath the detached retina, for the purpose of permitting the sub-retinal fluid to escape, is one of the earliest surgical procedures. Many operators combine single or multiple incisions of the retina with the above-mentioned procedure, permitting the sub-retinal fluid to pass into the vitreous chamber, with the hope that by restoring the volume of the contents of the vitreous chamber, replacement of the retina would follow, and permanent adhesion between retina and choroid would result from the exudation and irritation provoked by the incisions. Bull (*Trans. Am. Oph. Soc.*, 1894, p. 382), recognizing the fact that the contraction of cicatricial bands that have formed in the vitreous is a factor in the production of detachment of the retina in certain cases, resorts to division of these bands by incision through sclera, choroid, and retina, permitting the sub-retinal fluid to escape into the vitreous chamber. He reports favorable results in the cases operated on. Bull warns against the attempt to divide vitreous bands that are vascular. In the belief that shrinking of the vitreous humor, accompanied by traction from filamentous bands uniting retina and vitreous, are responsible for detachment of the retina in many of the spontaneous cases, Deutschmann (*Beiträge z. Augenheilk.*, Vol. XX, p. 1) employs a modified form of Bull's procedure. In the more recent cases the point of a thin, double-edged knife is passed through the sclera, choroid, and retina, at or near the periphery of the detachment, and is carried to a point very near to the opposite wall of the globe. It is then swept through the vitreous just over the detachment and the filamentous bands divided. The retina is incised in two or more places; a portion of the sub-retinal fluid passes into the vitreous chamber and a portion passes outward through the scleral wound. In some cases Deutschmann has resorted to the injection of the vitreous humor of a rabbit into the vitreous chamber of the human eye by means of a Parvez syringe. In old cases of detachment, in order to establish marked adhesive inflammatory reaction between retina and choroid, the fine point of a Paquelin cautery is employed to pierce the sclera and choroid, passing into the sub-retinal space, either before or after the incisions above referred to are made. A number of cases are reported which have been under observation from a few months to a number of years. The reaction from the operation is said to be slight, and the results very favorable. Application of the galvano-cautery point by puncture, has been made. The injection of irritating solutions between retina and choroid, after permitting the sub-retinal fluid to escape, notably the injection of one or two drops of Lugol's solution, as advocated by Schoeler, of Berlin, has been extensively tried. Recently, Terson (*Anal. d'Oculistique*, July, 1895, p. 23) has made something of a study of the causes of detachment of the retina. He is of the belief that many of the cases of detachment are due to sub-retinal exudation from the choroid and that progressive myopia, primary changes in the vitreous —either liquefaction or the formation of connective tissue bands—do not possess the importance as causes, that have heretofore been assigned to them.

Terson believes that in electrolysis we possess a means of treatment for detachment of the retina that is valuable. The positive pole only is introduced into the eye; for the reason of its greater coagulating effect as compared with the negative pole, and because the wound made by

the needle of the positive closes more quickly than that made by the needle of the negative pole. Bipolar electrolysis, as employed by Schoeler and others, is not thought to possess the advantages that belong to the positive pole when used alone. A strong platiniridium needle with a gutta-percha handle is employed. The point of the needle is passed through the sclera and choroid into the sub-retinal space, and a current of five milliamperes is permitted to pass for one minute. Of the twelve cases reported, the detachment had been present from two to eight weeks in eight; in two, the time was not given; in one, three years; in one, eight days. Of the first eight cases temporary improvement occurred in three; more lasting improvement in five cases. In the case of three years' duration irido-choroiditis followed the operative procedure. In one other case there was no improvement, and in one, temporary improvement only. In the detachment of eight days' standing, a permanent recovery is reported. The eye in this case was extremely myopic. Ultimate vision of $\frac{1}{12}$ was obtained. The results as quoted above are encouraging, but we must await the report of the experience of other operators before judging the value of the procedure.

John E. Weeks, M.D.

ECHOES AND NEWS.

There is reported from South Bound Brook, N. J., a sad case of the poisoning of four young children, who had mistaken wild parsnip for horseradish. One child died before medical aid could be procured, and the other three were made dangerously ill.

The annual report of the registrar-general of Great Britain for 1895 shows that the death rate was lower last year in that country than in any other year since its mortality statistics have been recorded. This is an important statement. It shows that the average health of one of the most crowded countries in the world is steadily growing better. The lowered death rate indicates that where the race against death is the sharpest the average bodily condition of men and women is most comfortable. In Great Britain the vast majority of the people live in the cities and large towns, and the decrease in the death rate points out that sickness and loss of life in these places are largely under control. It would appear from this statement that where civilization is best it has most influence over the conditions of life.

A non-poisonous match has been invented by a distinguished chemist, M. Pouteaux. Permanganate of potash and acetate of amyl are among the inoffensive ingredients. At the Pasteur lucifer match manufactory the combination has been tested with satisfactory results. The matches are easily made, without the slightest danger to the factory hands. They ignite readily, there is no danger of explosion when stored, and the disagreeable odor common to lucifer matches is in these replaced by that of aniseed.

The New Zealand government has sent to London the draft of a bill which provides for the strict exclusion of consumptives from the islands, just as individuals having smallpox, leprosy, or other contagious disease are now prohibited from landing by the existing laws. To better enforce this proposed act, it is provided that a heavy penalty be imposed upon the captain of any ship who may land a person suffering with phthisis.

A large addition to the Baltimore Medical College and the Maryland General Hospital is to be erected in the near future.

The executive council of Massachusetts has unanimously confirmed the nomination of Dr. Henry P. Walcott, chairman of the State Board of Health, as metropolitan water commissioner.

On March 21st Dr. M. M. Royer died suddenly at his home, 906 Warren avenue, Chicago, of some form of cardiac disease, which was wholly unsuspected by his friends and family. However, the previous week he had acquired a strong premonition of his approaching end, of which he had warned his family, and then prepared a brief biography, to which was appended detailed directions of the programme to be followed at his obsequies.

Governor Morton has appointed Dr. Theodore K. Tuthill, of No. 319 West Eighteenth street, as coroner for New York city, in the place of Coroner O'Meagher, deceased.

Dr. Frank Winders has been elected by the State Board of Medical Examiners of Ohio as their permanent secretary. He is a graduate of Bellevue Hospital Medical College of New York, in the class of 1895.

A more than ordinary degree of forethought was displayed by a lady, formerly of Staten Island, but now deceased, whose will is at present the subject of legal proceedings. In order to avoid the most common legal grounds for setting aside testamentary documents she subjected her mental condition to the investigation of five expert alienists, who became witnesses to her will, and certified to her soundness of mind.

The cause of caisson disease, or rather of the train of symptoms that has long been known to result from exposure of workmen to continued high atmospheric pressure in the construction of submarine masonry, is now

the subject of experimental investigation in France. M. Hersent, a civil engineer, expresses the firm conviction that the large sacrifice of life in the past has been due to the rapid variations in the degree of compression, brought about by ignorance or carelessness. He found that dogs could endure, without danger, a pressure of seventy-five to eighty pounds to the square inch for as much as five hours, provided that twenty-five minutes were occupied in gradually producing this amount of compression, and one and a half hours in "decompression," a uniform temperature being maintained. Practically the same experiments, with perhaps a more gradual change in the pressure, were carefully made upon workmen, with only a little lassitude, lumbago, and slight prickling sensations of the surface resulting. It was thus demonstrated that without overtaxing the workmen they can labor uninterruptedly for four hours or more under a pressure of seventy-five pounds or more; that is to say, at 150 to 175 feet below sea level, on condition that they should experience a very slow compression and "decompression," and that the temperature be uniformly maintained.

The New York coroner's bill is reported to be in danger of defeat, due to adverse pressure brought to bear by the present incumbents and others interested in political patronage. It has been referred by the judiciary committee to a sub-committee of three, who seem disposed to consider the influence of the present coroners, and are led to fear, furthermore, that the medical profession, as a class, are to reap improper benefits from the adoption of this bill. If the sub-committee can devise some method for allotting these appointments by others than the judges of the supreme court, it is thought that a favorable report on the measure is probable.

The Cornell Brain Association, to which we recently alluded, has its prototype in the Mutual Autopsy Society of Paris, which has been in existence since 1876 and numbers 100 members.

The Hon. Mr. Gallinger, in the United States Senate last week presented numerous petitions and papers from clergymen, physicians, and educators, in favor of setting apart a Government reservation for the benefit of persons suffering from pulmonary diseases, who might be benefited by a change of climate to the salubrious atmosphere of the Rocky Mountain region; and subsequently he also introduced a bill setting apart the Fort Stanton military reservation in New Mexico for a like purpose. He spoke in favor of the proposition, which is under the lead of the American Invalid Aid Society of Boston.

The Brooklyn Board of Aldermen recently received a communication from the Commissioners of Charities calling attention to the overcrowded condition of the County Hospital and the serious danger to the six hundred patients in case of fire. Permission was also asked for the immediate erection of a drug and supply building, nurses' quarters, a home for the convalescents, and administration offices. It was also suggested that an electric light plant be provided for the hospital. The communication was referred to a committee.

The *British Medical Journal* states that the falling off in the production of cod-liver oil this season will certainly advance the wholesale prices of this standard remedy. Reports from the Norway fisheries show rapid diminution in the annual supply that must shortly result in a total suspension of the product. Some quotations already indicate an advance of nearly 100 per cent. over last season.

Governor Bradley, of Kentucky, has appointed Dr. B. F. Porter, colored, third assistant physician to the Lakeland Insane Asylum. As he will have several wards containing white patients under his medical supervision, the Governor has been receiving rather unpleasant criticisms throughout his State.

Dr. E. W. Martin, Chief Inspector of Foods for the New York Board of Health, found tuberculous beef exposed for sale in the markets last week. The animals were procured at the New Jersey stock yards.

A "divine healer" named Schrader, is now visiting Cincinnati. The manner of his advent, together with his readiness to be extensively interviewed for the public press, evinces the instincts of the ordinary patent medicine man. Flowing robes, a crown of thorns, and the general cut of hair and beard, suggest an affected resemblance to approved likenesses of the Savior.

SOCIETY PROCEEDINGS.

KINGS COUNTY MEDICAL ASSOCIATION.

Regular Meeting, February 11, 1896.

THE CLINICAL ASPECT OF CHRONIC DIFFUSE NEPHRITIS. (SEE PAGE 367.)

DISCUSSION.

Dr. T. M. Lloyd: In relation to etiology, observers of large experience have been convinced of the importance of constant nerve strain, excitement, or worry, as prominent factors in the production of chronic kidney changes, often it may be preceded by a chronic endoarteritis. These factors are often associated with persistent use of alcohol, tobacco, or other excesses, but frequently without these excesses, in subjects of good habits, excepting perhaps, a relative excess of food as compared with exercise and outdoor air, operating for years.

The importance of painstaking care and intelligent use of the methods of diagnosis of kidney diseases cannot be too strongly insisted upon. Every one who has had a large experience in urinary examinations knows how imperfectly many examinations of the urine are made, often by otherwise skilful men. It is specially important that cases with mere traces of albumin be early recognized if we are to help our patients. This condition must be differentiated positively from the temporary or less serious conditions. One of the most important of these is the presence of nucleo-albumin, formerly included under the

designation of mucin, which is not differentiated in so many of the delicate tests for albumin. The presence of albumin in minute quantity necessitates a most skilful and often laborious search for the microscopical elements indicative of the various renal changes.

With the strictest attention in the use of the most delicate tests for albumin, certain forms of chronic kidney lesion may escape detection for long periods if an exhaustive examination in other particulars be not made, viz: the quantity per twenty-four hours with the specific gravity of the whole, estimation for urea, and careful microscopical search.

I wish to call attention to a very ready, practical test I have made much use of, which is the nitric-magnesian fluid of Roberts.

The test is prepared by mixing one part of the pure nitric acid with five parts of a saturated solution of the sulphate of magnesia, and filtering. The principal advantages claimed for it by Dr. Roberts are that it does not stain or soil the fingers, that it does not show a coloration of iodin, and, most important of all, that it is a more delicate test than pure nitric acid. It is used the same way as the latter, a drachm being poured into the bottom of the test tube, holding this nearly horizontal so that the two liquids do not commingle.

This test possesses this very great advantage: that it condenses more thoroughly the albumin than does the nitric acid. It often happens that the zone produced by the nitric acid will be light and fluffy, mucin, or the substance I have so often referred to, being directly in contact with it in considerable quantity, while that produced by the nitric-magnesian test would be condensed, compact, lardaceous, and clearly and sharply defined, the obnoxious mucin being more distinctly separated from it and above it. Such a compact layer can be taken with more confidence as a basis for the estimate of the quantity of albumin. In regard once more to the delicacy of this test I have found it to show the presence of albumin often diluting it to a point where nitric acid ceased to show it. From my experiments I believe it to be easily a third more sensitive than nitric acid.

This test does not absolutely distinguish albumin from mucin, or nucleo-albumin, when small traces of the former are present, in all cases; but the ferro-cyanide test, as recommended by Purdy and E. E. Smith, will help to differentiate. This test of Roberts being more delicate and definite than nitric acid, and free from some of the errors of the latter, notably the nitrate of urea zone. I have been in the habit of using it for some years as a companion test.

Notwithstanding the importance of the manifestation of albumina minima we should be careful in giving too serious a prognosis in certain cases till a sufficient time and repeated observations of the urine and the patient indicate the grounds therefore. Many of us remember to have given a very grave prognosis, and to have found, months or years after, the patient living in comparative comfort and apparent health. These occurrences are not infrequent with elderly people. The presence also of albumina minima, hyaline casts, etc., I have observed in young children when perhaps the only other abnormal condition evident was a slight degree of anemia, and which disappeared under appropriate tonic treatment, change of air, etc.

Dr. A. R. Paine: I have grown to be more and more impressed by the importance of chronic nephritis. In our profession we see more and more of the universal way in which it manifests itself, and I have learned to regard the kidneys with more and more suspicion as people pass middle life; there are so many different manifestations, and we find so many different neuroses for which we cannot account, which, after examination of the urine, we find explained. In obscure diseases of the circulatory system where we have no suspicion of the kidneys, before examining the urine, we often find in these organs the pathological explanation of them. Hence I have made it an invariable rule to analyze the urine with especial care in patients who have passed middle life. I consider that it is very important, as stated by the author, that there be regular systematic observation. The remarks concerning sciatica recall to me a case in which, when I first knew the patient, there was no sign of disease except the sciatica, and one might have thought that she was in perfect health; but at last I found that the kidneys were to blame, and now nephritis is approaching to the last stage. All of us know so many cases of this kind in people who are past middle life that I have, as I say, become suspicious. And, though I agree with Dr. Lloyd, when he says that we must not too completely doom the patient who has albuminuria, because I have seen many cases, even in elderly people, where one might think that the end must be near, who, by taking care of themselves, have improved and lived for years very comfortably, still I have noticed that generally they eventually die from this trouble.

Dr. L. A. W. Alleman: The subject which the President has presented in his address is one of the greatest general interest, and to me it is particularly so, because of the importance of the complete clinical picture, when considering ocular changes, which we suspect to be of renal origin. The more I see of these cases, the more I am impressed with the difficulty of making a positive diagnosis of nephritic retinitis. Typical cases are not common in practice, and the atypical ones so nearly resemble the changes which are found in other retinal lesions that we must often be guided more by the history and the evidences of similar changes in other organs due to the same causes than by the ophthalmoscopic examinations; and it is to the less pronounced symptoms, those upon which the President has placed special emphasis, that we must trust, for the cases which show ocular lesions are not, as a rule, those suffering with the grave cardiac and respiratory manifestations. The cases we see are often discovered in an examination for glasses in patients ignorant of any serious organic disorders, and in whom urinary examinations often fail to discover albumin without a most careful and persistent search. It is estimated that about 6 per cent. of all Bright's cases show retinal changes. I believe this is entirely too low a percentage. The cases where the more distressing general symptoms are present do not

note slight ocular defects, and no examination of the fundus is made.

From a few examinations made in the wards of a general hospital, taking all cases of chronic renal disease admitted, I am inclined to believe that such changes are present in a majority of advanced cases. The recurrent conjunctivitis described in the paper is, I think, the same condition which Jonathan Hutchison enumerates among the symptoms of gout, calling it the "hot eye." Conjunctival hemorrhages are often found in these cases, but are, as a rule, associated with retinal hemorrhages, and sometimes even precede them.

Dr. A. C. Brush: It seems to me that there is one question to be considered here: whether all these symptoms are due to the kidney lesion, or whether both are not due to the same general systemic poisoning. Samoli, ten years ago, pointed out the fact that brain-workers have an excess of phosphates in their urine, and sooner or later suffer from renal disease from the local irritation, and we know that such substances as alcohol and the poisons of rheumatism, gout, and the bacterial products found in other diseases are capable of causing severe renal trouble with their other manifestations. It is also believed that the ptomaines developed in digestive disturbances may be followed by kidney trouble. The earlier symptoms, too, are often those of a general neurasthenia due to the toxemia. It is these patients who complain of singing noises in the head, of hearing bells, of flashes of light and small objects before the eyes, of insomnia, irritability, loss of memory, neuralgias, and other disturbances of general sensation. It has been lately shown that 37 per cent. of the patients admitted to the asylum suffer from chronic renal disease, which is believed by some to be the cause of the insanity.

Dr. Bierwirth: I have not much to say in closing. I have discarded the test of which Dr. Lloyd spoke, as I have others of the contact method. I have for years discarded the nitric acid method, because it does not detect with sufficient accuracy. You do not know positively whether you have a trace of albumin or not, the difficulty lying in the fact that the coloring matter of the urine is so darkened by the nitric acid that a trace of albumin cannot be detected at the point of contact. The contact method always makes me feel uncomfortable, because it does not give me positive results, and I have to examine further with other tests.

As regards the progress of the disease, I thoroughly agree with Dr. Lloyd. There are elderly people, people of fifty or sixty years of age, who suffer from chronic Bright's disease, and who live very comfortably, but they must live in a certain way. It is absolutely essential for these people to stay indoors, say from October through the winter, and that is one of the reasons why it is well for them to live in an equable climate during the winter. A patient of mine died a week ago who had had chronic Bright's disease for years, and died just as a number of cases do. She had three attacks in one one month, and she died because she was exposed to a cold draft. The greatest trouble with cases of acute Bright's disease is that they occur in persons of active life who find it very difficult to realize that they have to take care of themselves. A man may live for ten, fifteen, or twenty years even, if he will only take good care of himself and live in the way which I have indicated. I have a patient who is a very good example of this. A woman who had always been well until the disease of the kidneys appeared and who could not understand the importance of taking care of herself, She had several very severe attacks of acute exacerbation and nearly died in one of them, and ever since then she has been extremely careful and consequently fairly well. That is one of the cases of elderly people who live very comfortably and live a long time. But as I say, persons of active business habits have great difficulty in accustoming themselves to taking care of themselves, and thus there are dozens of men under ground who should be alive; men who led active business lives, to whom I said five years ago that they must stop, they must have rest, they must give up and go home and take care of themselves; they could not accustom themselves to it and so they have suffered the consequences. I know a case of a gentleman over seventy years of age who could not for months get it into his mind that he must stay indoors, until he had a couple of attacks, which were attributed to his having been exposed and taking cold, and he has now learned to take care of himself and is living very comfortably, although, in my judgment, he has very serious kidney trouble. Another very important point which Dr. Lloyd has made and in which I agree with him, is the necessity for frequent and continued examination for hyaline and granular casts. I have seen cases of simple albuminuria of which he speaks, and I regard them with a great deal of suspicion. I think you will find that most of them, if you watch for a sufficiently long time, will be very apt to prove cases of Bright's disease and not simply cases of functional disturbances. This disease begins in a most insiduous way and it may take years—four, five, or six years—before it shows itself plainly. If a patient is in active business life it is hard for him to understand at once that he has to take care of himself, but if he does, the disease makes but slight progress. I have been frequently struck with the uselessness of the examination of urine in life insurance, because a man may present himself before the examiner before or after a meal, or between meals, or far from them, and the urine taken in these cases, especially in examinations of persons past middle life, are practically useless, because sufficient time cannot be given to them to make the examination properly. In my judgment and observation, life insurance examination of the urine, therefore, is practically useless. The patient may, if he is honest, give a correct history of himself or he may not. I remember a man whom I examined. The only thing that I could find was a rapid pulse—112—but his urine contained about 5 per cent. of albumin. This was a case of a man who thought himself perfectly well, and who had gone on for years without any knowledge that he had anything serious the matter with him. Again there are many cases where people suddenly develop symptoms of coma. I recall the case of a gentleman who felt drowsy, and from this he rapidly drifted into coma and from coma into death, and after death it was found that he had marked disease of

the kidneys, yet during life he had never given an exhibition of a single symptom. These repeat themselves over and over again. They are not of very rare occurrence and that is why I lay so much stress upon the importance of frequent examinations of the urine. In many of these cases they only show a trace of albumin even up to the time of death. I have known cases to end fatally in which there was nothing more than a trace of albumin up to the time of death, and so I repeat: this all shows us the extreme importance of great care in examinations of urine, and especially of making frequent tests for urea.

REVIEWS.

The Year-book of Treatment for 1896. A Critical Review for Practitioners of Medicine and Surgery. 12mo, 484 pages. Philadelphia: Lea Brothers & Co., Publishers, 1896.

This little volume, which is compiled by several of the best known clinicians of Great Britain, has, unlike many compilations that pass as medical literature, a real purpose. It gives within the confines of 500 pages a review and an estimation of all that has been done in the civilized world to advance the purpose of our art and our science as observed by men who are capable of dispassionate criticism. A careful examination of the Yearbook for 1896 shows it to be abreast, if not in advance, of its predecessors. A more equitable allotment of space to subjects of equal importance might have been made by the editor. For instance, the diseases of the heart and lungs are given sixty pages, while fourteen are allotted to diseases of the eye, and thirty to diseases of the mind and nervous system, and more than one-half of the volume is taken up by a consideration of general and special surgery.

The chapter on anesthetics is carefully prepared, and particularly useful are the illustrated pages devoted to new apparatus for anesthesia. The pathogenesis of diphtheria and the present status of antitoxin in the treatment of this disease are considered in praiseworthy detail. It is admitted by every one who has had experience with antitoxin treatment, that one of the first claims of the advocates of the antitoxin plan of treatment to have been found wanting was that it would diminish the frequency of paralysis after diphtheria. Dr. Phillips quotes approvingly evidence to show that paralysis becomes more frequent after treatment.

The universal activity in operative surgery, and its triumphs, are set forth convincingly, yet we notice a few serious omissions. The notable address of v. Bergmann before the Congress of German Surgeons last year, the really wonderful report made by Kocher, on operation for goitre, and some other important contributions have been overlooked.

Another matter that cannot fail to strike the critical reader of medical literature is that sufficient discrimination is not made between contributions whose apparent aim it is to advance the science of medicine, but whose real purpose is to contribute to the selling qualities of the substance or preparation which the writer claims to have found so useful, and real, genuine, honest expressions of experience and judgment. It is a matter of regret that physicians are found who will prostitute their names and their reputations in this manner, but they are, and we are powerless to prevent it. We can, however, avoid disseminating their canards, and we expect their critics and mentors to do so.

The Yearbook is to be congratulated on the comparative freedom which it has from such references, but it may be still further purged.

We have no hesitancy in saying that this little volume will be found most serviceable to the general practitioner.

An appended selected list of new books is a commendable feature.

A Text-book of Forensic Medicine and Toxicology. By Arthur P. Luff, M.D., Lecturer on Medical Jurisprudence and Toxicology in St. Mary's Hospital. In two volumes, small 8vo. Vol. I, 416 pages. Vol. II, 334 pages and Index. London and New York: Longmans, Green & Co.

This is a compact and useful compendium of medical jurisprudence and toxicology. It is illustrated with twelve full-page plates and fifty-seven figures in the text. One of these plates, representing various blood-spectra, is in colors. All the illustrations are well executed and the general typography is excellent.

The matter of the book is well selected and arranged, and follows the usual order of treatises of this character. The toxicology covers over 300 pages, being all included in the first volume. This is not an undue proportion for so important a subject. Experience in this country shows that physicians are more liable to err in the diagnosis of cases of poisoning, or, at least, to mistake them for disease, than in almost any other field of work. We are glad to note that a considerable space is given to Reinsch's test for arsenic. The ingenious method described for securing the crystalline sublimate on the surface of a glass slip, so that it can be examined under the microscope, will be of much use. Dr. Luff does not think it possible to determine from the measurements of the corpuscles that the blood was positively human blood, but thinks that it is only safe to say that it is mammalian blood. This is a wise and conservative view. Much injury has been done to the cause of expert testimony by the readiness of certain experts to testify positively in this and similar cases in which positiveness cannot be attained.

The treatment of all the topics seems to be excellently proportioned, and we consider the work to be a most valuable addition to the literature of the subject.

Medical and Surgical Report of the Children's Hospital, 1869–1894. Edited by T. M. Rotch, M.D., and Hubert L. Burrell, M.D. Boston: Published by the Board of Managers, 1895.

This handsome volume of 367 pages is published with the view of "presenting to the community, first, the history of an institution organized and maintained for the care of sick and disabled children; secondly, in order to show, by the contributions of the members of its medical staff, how much good work has been done, and the most efficient methods known to medical science of

accomplishing its object; and, thirdly, of offering carefully prepared articles, based largely on the practice of the hospital, on various topics of importance in the science of medicine." For this purpose the matter is divided into three parts, under the headings "Administrative," "Medical," and "Surgical." Of these the last takes up fully two-thirds of the volume, and presents quite a comprehensive view of this branch of the hospital's work and of its methods of treatment. Orthopedics naturally holds a prominent place, and is quite fully illustrated. The medical division embraces only seven short papers, which, however, are of unusual interest. It is to be regretted that greater space was not devoted to this portion of the hospital's service.

The volume is a handsome specimen of bookmaking, and is creditable alike to the institution whose work it thus brings to public notice and to the various members of the staff whose unselfish labors have made the hospital what it is to-day.

The American Year-book of Medicine and Surgery. Being a yearly digest of scientific progress and authoritative opinion in all branches of medicine and surgery, drawn from journals, monographs, and textbooks of the leading American and foreign authors and investigators. Collected and arranged with critical editorial comments by a large corps of collaborators (twenty-seven) under the general editorial charge of George M. Gould, M.D. Profusely illustrated with numerous woodcuts in text and thirty-three handsome half-tone and colored plates. Large, 8vo. Pp. 1183. W. B. Saunders, Philadelphia, 1896.

If professional writers ever read, they get a part of their just punishment when, in the avalanche of literature falling about us on every side, they may occasionally try to look up a special subject or find a certain article. It is not that too much ink is spilt, but because it is too widely spilt in small channels and gullies which never unite to make a navigable stream, that we complain.

It is, therefore, with gratitude that we hail all properly constructed "Year-books" in which men of wide reading, of practical knowledge, and capable of judicial criticism collect a summary of each year's medical progress. To a certain extent they save us from the clutches of those flatulent scribes who write on such subjects as "Unilateral Polymerism of the Fimbriæ of the Fallopian Tube as a Cause of Climacteric Scoliosis," or "The Treatment of Sterility by the Instillation of the Fresh Juice of an Extradomiciliary Orchid." Of course, we cannot depend wholly upon "year-books," but they lighten our running struggle with current medical literature.

As to the present publication, the distinguished names connected with the *résumé* of each subject and the scholarly and professional eminence of the editor are sufficient guarantees for its excellence. By no means of the least worth are the editorial comments (enclosed in brackets) upon new suggestions or matters in dispute.

It would seem as though hardly enough space, fifty-four pages, had been allotted to materia medica, experimental therapeutics, and pharmacology, but a closer perusal may demonstrate that the deficiency is made good under each specialty.

The work would be improved if a uniform system of weights, measures, and thermometric readings had been employed throughout. As it is, grains and grams, Fahrenheit, and Centigrade, appear, sometimes on the same page.

The publisher's work has been well done. The print is large and clear, the illustrations copious and demonstrative.

Elementary Technique in Histology and Bacteriology. By Ernest B. Hoag, A.B., B.S., Instructor in Zoölogy and Physiology, Throop Polytechnic Institute, Pasadena, Cal., and H. Kahn, Pharm. (Mich.), Assistant Demonstrator in Bacteriology, Northwestern University Medical School, Chicago. E. H. Colegrove & Co., Chicago, 1896.

This is a compend of 130 pages for beginners in histology and bacteriology, describing the various methods of staining and preparation of tissue for microscopic study. No attempt is made to introduce descriptive histology. The book is poorly printed, and for a work intended for beginners contains too many technical abbreviations. It is, however, up to date, and will no doubt be useful to those for whom it was intended.

ANNOUNCEMENTS.

MEETING OF THE AMERICAN MEDICAL ASSOCIATION.

The forty-seventh annual Session of the American Medical Association will be held in Atlanta, Ga., on Tuesday, Wednesday, Thursday, and Friday, May 5, 6, 7, and 8, commencing on Tuesday, at 10 A.M.

OFFICERS OF SECTIONS.

1. Practice of Medicine.—Wm. E. Quine, Chicago, Ill., chairman; DeLancey Rochester, Buffalo, N. Y., secretary.

2. Obstetrics and Diseases of Women.—J. Tabor Johnson, Washington, D. C., chairman; Reuben Peterson, Grand Rapids, Mich., secretary.

3. Surgery and Anatomy.—C. A. Wheaton, St. Paul, Minn., chairman; Wm. L. Estes, South Bethlehem, Pa., secretary.

4. State Medicine.—Chas. H. Shepard, Brooklyn, N. Y., chairman; Elmer Lee, Chicago, Ill., secretary.

5. Ophthalmology.—Lucien Howe, Buffalo, N. Y., chairman; Frank Allport, Minneapolis, Minn., secretary.

6. Diseases of Children.—A. C. Cotton, Chicago, Ill., chairman; A. J. Work, Elkhart, Ind., secretary.

7. Dental and Oral Surgery.—R. R. Andrews, Cambridge, Mass., chairman; Eugene S. Talbot, Chicago, Ill., secretary.

8. Neurology and Medical Jurisprudence.—Thos. D. Crothers, Hartford, Conn., chairman; W. J. Herdman, Ann Arbor, Mich., secretary.

9. Dermatology and Syphilography.—L. D. Bulkley,

New York, chairman; T. C. Gilchrist, Baltimore, Md., secretary.

10. Laryngology and Otology.—G. V. Woolen, Indianapolis, Ind., chairman; M. R. Ward, Pittsburgh, Pa., secretary.

11. Materia Medica and Pharmacy.—F. E. Stewart, Detroit, Mich., chairman; W. B. Hill, Milwaukee, Wis., secretary.

12. Physiology and Dietetics.—H. Bert Ellis, Los Angeles, Cal., chairman; Henry Salzer, Baltimore, Md., secretary.

WM. B. ATKINSON,
Permanent Secretary.
BROAD AND PINE STREETS, PHILADELPHIA.

THE CARTWRIGHT LECTURES.

THE Cartwright Lectures of the College of Physicians and Surgeons for 1896 will be given by George S. Huntington, A.M., M.D., Professor of Anatomy in the Medical Department of Columbia University, New York.

1. Lecture, Wednesday, April 8th.—Morphology of the Ileo-colic Junction and Large Intestine in Vertebrates.

2. Lecture, Wednesday, April 15th.—Evolution of Human Cecum and Vermiform Appendix, and Probable Lines of Derivation of the Corresponding Structures in the Other Vertebrates.

3. Lecture, Wednesday, April 22d.—Morphology of the Bronchial System and Its Relation to the Pulmonary Vascular Supply in Mammalia.

The lectures will be given in the hall of the New York Academy of Medicine, 17 West Forty-third Street, on the above dates, at 8.15 o'clock, P.M.

Committee: D. Bryson Delavan, Wm. K. Draper, Saml. W. Lambert.

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FROM FEBRUARY 1ST TO MARCH 16TH, 1896.

MURRAY, R. D., Surgeon. When relieved at Tortugas Quarantine, to proceed to Mobile, Ala., and assume command of service, February 19, 1896.

PECKHAM, C. T., P. A. Surgeon. To proceed from San Francisco Quarantine to Port Townsend, Wash., and assume command of service, February 6, 1896.

KALLOCH, P. C., P. A. Surgeon. When relieved at Cincinnati, Ohio, to proceed to Charleston, S. C., and assume command of service, February 6, 1896.

WILLIAMS, L. L., P. A. Surgeon. When relieved at Charleston, S. C., to report at Bureau, and then to proceed to Tortugas Quarantine and assume command of station, February 6, 1896.

VAUGHAN, G. T., P. A. Surgeon. Granted leave of absence for seven days, February 17, 1896.

COBB, J. O., P. A. Surgeon. When relieved at Port Townsend, Wash., to proceed to Cincinnati, Ohio, and assume command of Service, February 6, 1896.

GEDDINGS, H. D., P. A. Surgeon. When relieved at South-Atlantic Quarantine, to report at Bureau for duty, February 6, 1896.

ROSENAU, M. J., P. A. Surgeon. To assume command of the San-Francisco Quarantine, February 6, 1896.

NYDEGGER, J. A., Assistant Surgeon. To proceed from Washington, D. C., to Reedy Island Quarantine, for special temporary duty, February 17, 1896. To report at Bureau preparatory to assuming command of South Atlantic Quarantine, February 19, 1896.

VAUGHAN, G. T., P. A. Surgeon. Leave of absence for seven days, granted February 17, 1896, revoked February 27, 1896.

GUITERAS, G. M., P. A. Surgeon. Directed to proceed, on March 25, 1896, from Gulf Quarantine Station to Key West, Fla., and assume command of Service, February 27, 1896.

SMITH, A. C., P. A. Surgeon. To proceed from Memphis, Tenn., to Gulf Quarantine for duty, February 25, 1896.

YOUNG, G. B., P. A. Surgeon. When relieved at Key West, Fla., to proceed to Memphis, Tenn., and assume command of Service, February 27, 1896.

WICKES, H. W., Assistant Surgeon. To assume temporary command of Service at Memphis, Tenn. Upon being relieved, to rejoin station at New Orleans, February 24, 1896.

HAMILTON, J. B., Surgeon. Granted leave of absence for four days, March 16, 1896.

IRWIN FAIRFAX, Surgeon. To inspect service at Havana, Cuba, and quarantine stations in the South, March 2, 1896.

CARRINGTON, P. M., P. A. Surgeon. Granted leave of absence for thirty days, March 16, 1896.

NYDEGGER, J. A., Assistant Surgeon. To Report at Bureau for Instructions, March 6, 1896. To proceed from Washington, D. C., to South Atlantic Quarantine and assume command March 7, 1896.

PROCHAZKA, EMIL, Assistant Surgeon. Granted leave of absence for ten days, March 11, 1896.

RESIGNATION.

STRAYER, EDGAR, Assistant Surgeon. Resignation accepted, to take effect February 14, 1896.

BOARD CONVENED.

Board to examine and report on schedule of subsistence for seamen on merchant vessels of the U. S., to meet in Washington, D. C., March 16, 1896. Surgeon P. H. Bailhache, chairman; P. A. Surgeon C. E. Banks and P. A. Surgeon J. J. Kinyoun, recorders.

CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FROM FEBRUARY 27TH, 1896, TO MARCH 30TH, 1896.

February 27.—Assistant Surgeon J. C. ROSENBLEUTH detached from the Naval Laboratory and ordered to the "Raleigh."

Assistant Surgeon E. M. SHIPP detached from the "Raleigh" and ordered to the "Vermont."

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 25, 1896, TO MARCH 30, 1896.

The leave of absence on surgeon's certificate of disability, granted Captain Benjamin Munday, Assistant Surgeon, is extended two months, on account of sickness.

Leave of absence for one month, to take effect upon his relief from duty at Jefferson Barracks, Missouri, is granted Major Robert H. White, Surgeon.

The following named officers of the Medical Department are relieved from duty in Washington, to take effect upon the completion of the present course of instruction at the Army Medical School, and are assigned to duty at the following named stations:

First Lieutenant Thomas J. Kirkpatrick, Assistant Surgeon, Fort Columbus, N. Y., for temporary duty.

First Lieutenant John H. Stone, Assistant Surgeon, Fort Leavenworth, Kan.

First Lieutenant Irving W. Rand, Assistant Surgeon, Fort Apache, Ariz.

First Lieutenant Powell C. Fauntleroy, Assistant Surgeon, Fort Riley, Kan.

First Lieutenant James S. Wilson, Assistant Surgeon, Madison Barracks, N. Y., for temporary duty.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXVIII. NEW YORK, SATURDAY, APRIL 11, 1896. No. 15.

ORIGINAL ARTICLES.

THE TREATMENT OF THE INDIGESTION OF STARCHY FOODS.[1]

BY REYNOLD W. WILCOX, M.D., LL.D.,
OF NEW YORK;
PROFESSOR OF CLINICAL MEDICINE AND THERAPEUTICS AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; VISITING PHYSICIAN TO ST. MARK'S HOSPITAL.

THE proper treatment of this form of indigestion takes into consideration its causation. As has been said at another place,[2] the prophylaxis comprises the limitation of the starches ingested, insists upon thorough mastication, which results in complete insalivation, because in this way is the output of saliva increased, and the taking of starchy foods in as dry a condition as is possible. By giving careful attention to these conditions, a very considerable number of instances of the indigestion of starchy foods can be relieved. This is the extent to which the treatment of so-called buccal dyspepsia can go in the way of prevention.

The treatment of the indigestion of starchy foods must take into consideration the acidity of the stomach contents, the amount and character of the pancreatic fluid, the influence of intestinal micro-organisms, the deficient or exaggerated peristalsis, and the absorption of the converted starch.

Too great acidity of the gastric contents is unfavorable to starch conversion, because: first, it limits the time during which the ptyalin from the salivary glands acts in the stomach, at best but half an hour, or abolishes it altogether; secondly, the outpouring of an excessively acid fluid from the stomach into the duodenum delays and markedly interferes with the re-establishment of starch conversion by the action of the amylopsin of the pancreatic fluid. In these cases the testing of the stomach contents gives a ready solution to the problem, and the neutralization of the excess of acid by sodium bicarbonate in dose from five to a hundred grains, in time varying from immediately to two hours after eating, will rectify this error. Recent papers have shown the harmlessness of even the long-continued use of large doses of this drug; and, further than this, the favor in which this remedy is held by many practitioners is due, not so much to its beneficial effect upon gastric, as to its secondary action upon intestinal digestion. In these cases not only must the proper dose be ascertained for each individual, but the time for its administration is equally important. The methods for ascertaining the motility of the stomach have been so frequently of late the subject of study by clinicians that it is not necessary for me to discuss them at this point. In passing, it is worthy of remark that the action of sodium bicarbonate is solely in neutralization of the free hydrochloric acid in the stomach, the important cause of interference with starch conversion; but it is probably without effect on the acids in organic combination.

Of disturbances of the motor functions, constipation is the rule in imperfect starch conversion. The best method of overcoming this is the administration of a saline in conjunction with an alkali, the latter assisting in the process of conversion. Further than this, as both Wöhler and Miahle have pointed out, the administration of salines will diminish the urinary acidity and quite likely also increase the normal alkalinity of the intestinal contents. The saline, which I have used by preference, is sodium phosphate (the normal, not the acid phosphate) in from 40 to 120-grain doses, to be taken in a full glass of hot water on rising in the morning. To this dose is added 15 to 40 grains of sodium bicarbonate. The advantage which the phosphate possesses over the sulphate is that it is distinctly less disagreeable in taste. As an alternative to these drugs I have used cascara sagrada in various preparations, in sufficient dose to secure a full movement, but I am not satisfied that its action is so beneficial. If gastric acidity is high, then we must in addition administer large doses of sodium bicarbonate during, or immediately after, each meal. Haidenhain has shown that alkalies facilitate pancreatic digestion, and this is the probable explanation.

Diarrhea is by no means common. It is generally due either to obstinate constipation, and alternates with it, or to abnormal activity of the micro-organisms. In the first case, as a rule, hard masses are found in the stools; in the second, the passages are watery, containing mucus and are of

[1] Read before the Section on General Medicine of the New York Academy of Medicine, February 18, 1896.

[2] MEDICAL NEWS, Vol. LXVIII, p. 182.

bad odor. If the diarrhea is due to the irritation produced by hardened masses, thorough purgation by the official compound carthartic pill followed by the sodium phosphate mixture is sufficient. If it is due to fermentation, a preliminary purgation with castor oil should be followed by the use of intestinal antiseptics. In either case no opium nor any of its alkaloids should be administered, for these only give temporary relief and lay the foundations for a worse condition than previously existed. The so-called intestinal astringents are equally useless. When the fermentation is marked, the expulsion of gas and pain are prominent symptoms. The treatment for the associated diarrhea is given above. In addition intestinal antiseptics should be continually administered. Since the commencement of my studies in 1884, I have made use of a large number of drugs, and their various disadvantages have been determined by clinical observation. Following Bouchard, we can say that naphthol has the best bacteriological basis for its therapeutic use. On the other hand, it is locally irritant, and it also increases the chlorine and generally the hydrochloric acid of the stomach, thus interfering with starchy digestion. Bismuth salicylate is not open to these objections, but unless the kidneys are healthy, this, as well as the other salicylates, is contra-indicated. Another disadvantage is, that this decomposes in the stomach, setting free the salicylic acid. Further, as Gley has shown, unless the pancreatic fluid and bile are discharged in sufficient amount into the duodenum so that distinct alkalinity is secured, the breaking up of such compounds as salol does not take place, and thus the salicylates may be useless. Salol presents another objection from the carbolic acid which it contains. I have used bismuth naphtholate with much satisfaction in these cases; it is not irritant and certainly limits the amount of gas formed, the offensiveness of the discharges, and decreases pain when caused by intestinal distention of gas. The dose varies from ten to twenty grains two hours after eating, administered as a powder or in gelatin capsules. Benzoyl-guaiacol has been used in a few instances, but not with the same success. The importance of intestinal antisepsis does not alone lie in the prevention of gas-formation, diarrhea, and pain, but also in the prevention of auto-intoxication from ptomaine absorption. By these means also the remote effects of systemic poisoning, the fecal anemia of Clark, neuralgia, vertigo, and the mental symptoms are obviated, and the results of the action of the micro-organisms of proteids resulting in indol, phenol, and skatol, and other aromatic bodies are minimized. The proper method of dealing with flatulence accompanied by pain is outlined above. For impatient individuals, while we are evacuating the offending material and establishing antisepsis of the digestive tract, a plan for affording speedy relief, and one which will not interfere with the action of the drugs in use, must be adopted. This is the administration of the concentrated tincture of avena sativa in a wineglassful of hot water every half hour until the pain is subdued.

The absorption of converted starch takes place rapidly enough if peristalsis is normal and mucus is not present in inordinate quantity. The latter is reduced in amount by the use of the sodium phosphate mixture in the manner directed.

The changes in character and amount of the pancreatic fluid have been the cause of various therapeutic expedients, and in obviating the results of these variations, physicians have found many apparently useful resources. At the outset pancreatin should be considered. The preparations, as found in the market, are often inert and, even if not, its action is destroyed in the stomach by contact with the acid gastric juice. To prevent this loss of action, Unna used pills coated with keratin. With this method of administration there is some question if these pills will not pass entirely through the intestinal tract with undissolved coating. It has been proposed to coat these pills with fused salol. The same objection applies to this practice as to the use of this drug for the establishment of intestinal antisepsis. The cases when it is most needed are those of deficient flow of pancreatic juice and diminished alkalinity of the contents of the duodenum, and so the salol would likely prove to be an impervious coating. Probably the best coating is an alcoholic solution of shellac, containing a sufficient quantity of balsam of tolu to impart a proper degree of elasticity, so that cracking of the coating during its drying is obviated; this was the suggestion of Flint. The use of pancreatin then appears to be rather in the preparation of predigested foods than administered as a drug.

Diastase, the maltine of Irwine (1785), Dubrunfault (1823-30), Payen, and of Persoz, has been the subject of much study. As made by Payen and Persoz, it is capable of dissolving, in several hours, fifteen to eighteen hundred times its weight of cooked starch. This as other diastases loses its property of converting starch in the presence of acid, but the degree of acidity requisite is less than the usual gastric acidity. Although its

action is favored by alkalies and alkaline salts yet the caustic alkaline solutions destroy it. As Hayem points out its action is best between 95° F. and 104° F., and the analogy between the vegetable and animal diastase (ptyalin) appears to be complete. The use of diastase from malt was insisted upon by Couteret (1870) who claimed to obtain great benefit from its use. In cases of gastric hyperacidity, when the action of the ptyalin is supended in the stomach and when that of the pancreatic fluid is lessened or prevented, the use of vegetable diastase administered with an alkali (sodium bicarbonate) gave good results. This practise was also sanctioned by Boas. For this purpose the following method of preparation has been employed: Three ounces, *i.e.*, three heaping tablespoonfuls of crushed malt, is well mixed with a half pint of cold water in a jug and allowed to stand from ten to twelve hours. The supernatant fluid was then poured off and strained through two or three folds of muslin until the filtrate becomes clear and bright. The yield is about six ounces. The disadvantages of this preparation were found in the necessity of its being freshly prepared. To preserve it, a few drops of chloroform were added to a tightly corked bottle of the liquid. When required for use it should be emptied into a saucer and left in a warm place, when, after two or three hours, the chloroform would be entirely evaporated. A liquid preparation of diastase, which is permanent, has been found in the shops for several years. It seems to possess but little amylolytic activity, due probably to the contained alcohol. The use of malt extracts in the treatment of amylaceous dyspepsia has yielded some very good results, but we are limited to the solid extracts. The liquid extracts generally contain so much alcohol and acids, the results of fermentation, that the action of the diastase is inhibited. At the same time, however, the feeble diastatic power of even the best of them, generally about five times their weight of dry starch, the large amount of inert substances, their deterioration with age, and the fermentation which the large amount of sugar (maltose) which they contain may give rise to, are all disadvantages. Further, the pharmaceutical difficulties in the way of using them in mixtures, are obstacles, but not insurmountable ones, to their use in elegant pharmacy. Some years ago (1891) I noted that a malt extract containing diastase in large percentage had been made by Jokichi Takamine, the Japanese chemist, but I have been unable to find pure diastase of value in the market until during the past year. My skepticism in regard to the value of diastase in the form of a dry powder was based upon the low starchy converting power of a foreign preparation. When I found that a diastase had been isolated by Takamine, and its value certified to by Lascar, I again experimented with the substance. This preparation, according to Smith and Tonkin, is made as follows: Bran of ordinary wheat is sterilized by heat so as to destroy any and all germs which it may contain. After cooling it is mixed with the Japanese fungus, the *eurotium oryzæ*, known as *taka-moashi*, in such proportions as experience shows to be most favorable for the development of the diastatic fungus, *taka-koji*. This mixture is kept at the same temperature during the whole of the forty hours it takes the fungus to attain its full development. The *taka-koji* is then washed in cold water, after which the pure diastase contained in the latter is precipitated in the form of a tasteless, odorless, and nearly white powder. Experiments have shown that this diastase possesses the remarkable power of, within ten minutes, converting into sugar one hundred times its weight of starch (estimated in the form of a dry paste), and, within three hours, fifteen hundred times its weight of starch. Its activity is increased by raising the temperature up to 131° F., but no higher. This action is more marked in neutral or feebly alkaline solutions, but is entirely absent in acid or strongly alkaline media. Even when the conditions are in the highest degree favorable the action of the diastase ceases when a certain amount of sugar has been formed. On placing the solutions in a dialyzer, so as to remove the sugar as fast as it was formed, it was found that the action of the ferment more closely resembles the process taking place in the organism, and that a much larger percentage of sugar was obtained than without it.

Lascar has found that he can convert with this diastase one hundred to one hundred and fifty times its weight of starch into a soluble state. Under proper conditions this first named amount is so thoroughly converted in four minutes that neither the iodin test nor the microscope can detect unconverted starch. The starch employed in most of his experiments was carefully washed arrowroot. The final result is, to a great extent, maltose. In this connection especial mention should be made that an undue employment of heat will destroy the action of diastase. The powder, as found in the market, appears to be permanent, and is used in doses of from one to five grains, as a powder or in gelatin capsules, during or after the meal. Since there is a possi-

bility of the activity of this drug being impaired in its passage through the stomach, although Thompson believes that vegetable diastase continues to operate in acid media, it may be administered as a pill, coated with an alcoholic solution of shellac, keratin, or salol, but the objections noted above will hold here as well. This method, however, I have found to be necessary.

The following cases, which are briefly reported, illustrate the classes in which we may reasonably hope to derive benefit from the administration of this drug:

I.—July 2, 1895, H. E., aged fifty-six years, dry-goods merchant, has suffered for years with dyspepsia. The attacks occur chiefly during his busy season, when hasty luncheons and irregular hours are the rule. On ascending the stairs the dyspnea is so severe that speech is impossible. The eyes are yellowish, dull headaches occur almost daily, and one to three nights each week. The heart is irregular, both in force and rhythm, there is much hepatic tenderness, and the abdomen is resistant and painful on pressure which gives rise to gurgling. Ten grains of calomel with twenty grains of sodium bicarbonate gave several copious, foul-smelling motions. A pill composed of podophyllin one-quarter grain, iridin one-half grain, and enonymin one grain, was ordered for each night. Bismuth naphtholate, five grains with taka-diastase, three grains in powder was given after each meal. 19th. The passages being softer and no longer foul-smelling, the bismuth is now omitted. The sleep and palpitation are much improved. August 9th. The improvement continues, and although cardiac irregularity persists, he is not sensible that his heart is abnormal. September 19th. All medication is now withdrawn, excepting the diastase which the patient is positive is also unnecessary. October 5th. On accidentally meeting the patient he announces that he is feeling in excellent condition, having taking no medicine for the past week. This patient might be classified as a buccal dyspeptic.

II.—July 27th, R. C., aged forty years, a merchant attending to a large enterprise, besides representing his organization in attempt to influence legislation, has been a pronounced lithemic for several years. He has been under the care of several physicians, who have generally pronounced him to be *brightique* and have prescribed a vegetable diet. He complains of various neuralgic pains, languor, disinclination to exertion, irritability of temper, constipation and flatulence. The cardiac first sound is booming, the second accentuated. The urine of sp. gr. 1018, without albumin, sugar, or casts, contains much calcium oxalate and broken-down epithelium. He is directed to make use of a mixed diet, avoiding, however, potatoes, drink one to three pints of an alkaline water between meals, daily, and to take outdoor exercise, short of fatigue. In addition he is to receive taka-diastase in two-grain doses with one grain of citrated caffein after each meal. August 10th. The patient reports but little change save that the constipation and flatulence are better. September 22d. The temper and capacity for work are much improved, and the work is done with less exertion. October 30th. The urine is now of sp. gr. 1022, with nothing abnormal excepting some calcium oxalate. December 9th. The patient reports great improvement over his condition six months ago and feels that he can dispense with medicine.

III.—July 30th, V. E., aged fifty-six, army officer, has been troubled for several months with morning nausea, constipation, distention of the stomach and bowels, more marked two or three hours after eating. There was dyspnea on exertion at all times, but after meals this became more marked, and with it was noticed palpitation. The patient was fleshy, a large eater, and was accustomed to the regular use of whisky in considerable amount, but never to the extent of inebriation. Physical examination revealed an irregular and intermittent pulse, a shortened, high-pitched and metallic first sound of the heart, an accentuated pulmonic second sound, a small liver, the area of flatulence being still more diminished because of the tympanitic percussion note which extended over the entire abdomen; the urine contained a trace of albumin and bile. The diagnosis was, fatty heart, cirrhotic liver, and duodenal indigestion. The patient was directed to limit his starchy foods, bread, potatoes, puddings, and diminish the amount of whisky, and at the same time dilute it. The sodium phosphate mixture was ordered for the morning, a pill of strychnin, one-twentieth grain and nitroglycerin, one-hundreth grain, to be taken thrice daily and immediately after eating, taka-diastase five grains in gelatin capsules. August 10th. The patient reports that the flatulence had markedly diminished, and with it the palpitation and dyspnea after meals; the constipation was lessened. The conditions, as found on physical examination, are as before, excepting that the abdominal distention and tympanitic percussion were not so marked. September 12th. The improvement has continued as regards the digestion, although the cardiac symptoms are but little better. October 1st. The constipation is so far relieved that the sodium phosphate can be omitted. The cardiac dyspnea is marked, and insomnia has become a prominent symptom. Beer is now used to the exclusion of whisky. 14th. Albumin has increased in the urine, and the cardiac symptoms are more severe, although the patient has a better appetite and does not complain of indigestion. The diastase is now reduced to two grains per dose. 25th. No dyspeptic symptoms are elicited upon questioning, therefore the diastase is omitted. November 16th. The circulatory disturbances are increasing, necessitating frequent

changes in treatment. About two weeks after this report the patient died quite suddenly. This patient suffered from incurable diseases of heart and liver, yet the betterment of his dyspeptic symptoms was too pronounced to be attributed solely to change in diet or to other medication.

IV.—August 20th, W. L., aged forty, lawyer, consulted me to be relieved of excessive flatulence, accompanied by constipation, which had existed for four weeks. He stated that he was a rapid eater, fond of bread and pastry, but of good habits. Physical examination revealed nothing but a sensitive and tympanitic abdomen. He was thin, nervous, and energetic. The urine showed an excess of alkaline phosphates. The sodium phosphate mixture was given, and five grains of taka-diastase in capsules with meals. Besides, the food was to be eaten slowly, masticated thoroughly, and the fluids at meals limited to twelve ounces. September 24th. The patient has been in the country since his first report, and states that he is greatly improved, but that at times only is he annoyed by flatulence. Sodium phosphate is to be omitted. October 17th. The symptoms are now entirely relieved, the urine is normal, and the diastase is omitted. This patient suffered from buccal dyspepsia, and a portion of the relief, at least, was brought about by regulating his habits of eating.

V.—August 3d, H. S., aged forty-four, builder, three days ago, while bathing, suffered from cardiac pain, oppression, and vertigo. For some months he had noticed abdominal pains after meals, flatulence, and dyspnea. At times his vertigo was so severe that he was unable to go about unfinished buildings. The patient was very stout, but his color was good. He was a hearty eater, and was much of his time in the open air. Beyond a rapid and slightly irregular heart-beat, nothing was found. The abdomen was fleshy, yet gave tympanitic resonance in the epigastric region. The liver was distinctly felt below the ribs. The patient's habits as regards large amounts of beer were corrected, and he was given taka-diastase in six-grain doses in capsules. 10th. The patient returns, complaining that the capsules gave rise to great irritation of the stomach, with nausea, and followed by vomiting. The dose was diminished to four grains and given in powder form. One-sixth of a grain of mercurous iodide (yellow) was given each night, and a half glass of Villacabras water in the morning. September 14th. The vertigo, flatulence, and breathlessness are improved. October 27th. The iodide and mineral water can now be omitted. The diastase is to be diminished to three grains during a continuance of the improvement. December 14th. The patient experiences so excellent health that all medication is omitted.

The foregoing cases, with a number of others, have been under observation a sufficient length of time for arriving at a fair conclusion as to the value of the remedy. In but two instances have been noted any markedly unpleasant results from the administration of diastase. One is recorded above; the other was of a young man who came to me suffering from acute intestinal indigestion from dietary indiscretion, whose symptoms were apparently unchanged, excepting increased nausea, after the administration of the remedy.

Nor am I certain as to the proper dosage; it is possible that one or two grains may be amply sufficient; on the other hand, I know of no reason why the maximum dose (six grains) as given above, may not be exceeded with safety. Theoretically that amount should be ample. Personally, I have come to prefer its administration in the form of a powder, and in that form it seems to retain its properties. All important is the diagnosis, that it shall be exact. Accessory means for the relief of by-symptoms should not be neglected.

We may fairly conclude that taka-diastase is useful:

1. In many cases in which the symptoms were wrongly attributed to proteid indigestion.

2. In the vast majority of cases as a substitute for the inefficient pancreatic extracts, malt mixtures and various combinations hitherto employed.

3. For the same relief of amylaceous dyspepsia, which, in the case of proteid indigestion, is obtained by acids and pepsin.

4. As a successful method by which the patients can preserve their nutrition upon a mixed diet.

749 Madison Avenue.

TARSAL DEFORMITIES IN CONGENITAL TALIPES EQUINO-VARUS.

By W. ROSS MARTIN, M.D.,
of Omaha, Neb.;
Recent House Surgeon to the Hospital for Ruptured and Crippled, New York; Professor of Bacteriology and Medical Chemistry John A. Creighton Medical College; Orthopedic Surgeon to St. Joseph's Hospital, Omaha.

The various forms of congenital club-foot may be thus classified for convenience of study:

Simple	Lateral	Varus. / Valgus.
	Antero-posterior	Equinus. / Calcaneus.
Compound	Equinus	Varus. / Valgus.
	Calcaneus	Varus. / Valgus.
Other forms	Cavus.	
	Planus.	
	Non-deforming (Shaffer).	
	Neuromemesis.	

As the non-congenital forms are not to be con-

sidered in this paper, they will be dismissed with the simple mention of their grand divisions: simple acquired, paralytic, and traumatic.

The proportion of cases of club-foot to all births is 1 to 806. Talipes equino-varus is by far the most frequent—three-fourths of all cases occur in both feet oftener than in one, the right oftener than the left, and is almost twice as frequent in males as females.

The etiology is wrapped in obscurity, its elucidation depending upon the data furnished by comparative physiology, pre-natal disease, and embryological research. In this there is found a vast field for theoretical speculation. The cause has been variously estimated under the heads of maternal impressions, of which no case has been reported; and heredity, which has undoubted influence, but is not generally traceable except in marriage of blood relatives. Statistics show one in 164 of the latter, against one in 1903 births from other marriages.

The chief theories are: (1) that of mechanical or intra-uterine pressure; (2) that of pre-natal disease or the musculo-nervous theory, and (3) the arrest of development or osseous theory. All of these have fallen into the background to give place to the fourth of non- or retarded rotation, which is the latest. It is based upon embryological research and offers the best explanation yet advanced, being demonstrable, feasible, and scientific. It was first proposed by Berg, of New York,[1] announced independently by Parker and Shattuck,[2] confirmed by Schudder,[3] and is favored by Bradford and Lovett, Roberts, Ketch, Young, and others.

In his experiments Berg observed the position of the lower extremities at different periods of fetal life, and found that from their position (crossed and flexed) that all intra-uterine pressure was brought to bear directly upon the outer border of the leg and dorsum of the foot, causing the position of equino-varus, which he believes to be a stage in the normal development of every fetus. Its permanence is obviated by nature providing an inward rotation of the extremity, carrying the leg away from the abdomen of the fetus, placing the feet against the utering walls in extreme flexion, and the force of intra-uterine pressure directly upon them. The correction of this early varus depends upon the completeness of internal rotation, and upon its failure or incompleteness depends the deformity.

There is marked alteration in all the structures except the muscles, which at birth are almost always healthy, but soon atrophy from disuse. The deformity is a displacement inward of the anterior part of the foot; the displacement occurring at the medio-tarsal articulation and accompanied by alteration in form and position of the astragalus and os calcis. The scaphoid is not altered in form, but is drawn upward, inward, and backward by the tibialis posticus, the tibialis anticus and the extensor proprius pollicis muscles articulating with the inner side of the head of the astragalus, and may, in severe cases, articulate with the tip of the internal malleolus. A separate synovial sac has been found in this locality by Bradford and Lovett. The astragalus is rotated on its antero-posterior axis, tilted downward and forward, the tibia only articulating with the posterior part of its superior facet; while the anterior portion of this surface becomes prominent on the dorsum of the foot. The head and neck are turned obliquely inward and closely resemble the os calcis of apes, as described by Parker. "The normal angle, formed by a line drawn parallel with its external border and the sagittal axis of the body, amounts at birth to an average of 38 degrees, and in the adult healthy foot 26⅙ degrees. In congenital equino-varus it varies from 64 to 31, the average being 49.5 degrees. Owing to this obliquity the articular head is directed antero-laterally and has two facets instead of one, the larger of which articulates with the displaced scaphoid."[4]

The complex nature of the deformity, coupled with its frequent occurrence, renders at once apparent the necessity for an universal treatment, or, in other words, a treatment that is within the reach of not alone the orthopedic surgeons but the general practitioners as well. In the treatment of congenital club-foot there is no established rule, for the method the surgeon best knows is apt to give him the best result. Early in 1893, Dr. Gibney, surgeon-in-chief to the Hospital for Ruptured and Crippled, New York, called the attention of the hospital staff to the Wolff method of using plaster-of-Paris, and at his suggestion the treatment was carried out. The attention of the profession was first called to the Wolff method in a paper read before the Association of American Physicians in Berlin by Dr. Freiberg, of Cincinnati, and published in the Medical News October 29, 1892. Wolff first anesthetizes his patient, except in very young children, and in slight degrees of club-foot, and then by manual

[4] Young.

force brings the foot into as nearly the proper position as is possible without using undue force, and while it is held in this corrected position by an assistant, strips of rubber adhesive plasters are applied spirally around the foot, extending well above the ankle. This is done to aid in holding the foot in the corrected position until plaster-of-Paris is applied. As used in the cases here reported the treatment has differed from that first practised only in the omission of the anesthetic. As no attempt was made in these cases to reduce the deformity at the first sitting, no anesthetic or adhesive plaster was necessary. There is no difficulty experienced, even with the most ordinary assistance in applying the dressing, after which the patient remains undisturbed for twenty-four hours, when *redressment* can be commenced safely. Pain is most marked in the beginning of treatment, and for this reason only a little of the deformity should be corrected at the first two or three sittings. It is best at all stages of treatment to regulate the amount of twisting by the pain produced. In applying the dressing, first place a piece of double-faced canton-flannel along both the outer and inner borders of the foot extending over the malleoli. This offers protection to the bony prominences, which is especially required over the metatarso-phalangeal joint of the great toe and over the cuboid bone. Now two thicknesses of single-faced canton-flannel bandage are snugly applied to the foot and leg, extending to and including the tuberosity of the tibia. The plaster is now applied, extending quite as high as the bandage, thus grasping the tibial tuberosity, it prevents rotation which allows of effectual *redressment.* To avoid pain and swelling the toes should be kept in their normal relation to each other, only their tips should be exposed. The amount of plaster used is governed by the size of the member, usually one and one-half or two ordinary bandages will suffice, and should be applied in the usual manner. Now by grasping the leg in one hand and holding it firmly on the table the plantar surface is made flat by firm pressure with a small board in the other. This corrects some of the deformity and furnishes an even surface on which the child can walk. Real treatment, as before stated, is begun twenty-four hours after applying the dressing, as above indicated; first by cutting out a wedge-shaped piece of the plaster over the most prominent part of the deformity, the angles of this opening being united by a linear cut through the remaining plaster. In making this section, care should be taken not to pass so near the heel as to permit it slipping when the foot is twisted. But little force is now required to oppose the edges of the wedge-shaped opening in the plaster and effectually overcome a part of the deformity. The foot is held in this new position by an assistant while another bandage is applied by filling the space on the inner side of the foot with folds of the bandage, and carrying the whole by a figure of 8 around the foot and ankle. This holds the foot firm until the next treatment, when it is easily peeled off from the primary dressing which was dry when the stay bandage was applied. The succeeding treatments are done by simply enlarging the wedge-shaped incision and applying a new stay bandage. After three or four stretchings it will be found necessary to apply an entirely new dressing. When excoriations occur, and they are liable to be the result of pinching the skin, it is necessary to discontinue the treatment for some time, as excoriations from this cause are very difficult to heal. Continue the treatment until the foot is in the position of over-correction and then encase it in a silicate of soda dressing strengthened by a piece of light steel passing from the ball of the foot above the heel. Over this a shoe is worn. Wolff continues this dressing for six months.

Case I.—Norman M., aged 4½ years. Double equino-varus. Stands on outer border of left foot, with 45 degrees of inversion; right about 25 degress of inversion. July 15th, has Achillotomy, plantar fasciotomy, and twisting with Thomas' wrench of both feet. August 26th, has 35 degrees inversion of right and 15 or 20 degrees of left foot. Wolff method commenced. September 9th, deformity of right foot corrected at four

Case I.

BEFORE. AFTER.

sittings. September 15th, deformity of left at at eight sittings (see photograph before and after treatment).

Case II.—Robert C., aged nine years. Right talipes varo-equinus marked pes cavus. March 17th, Achillotomy, fasciotomy, and twisting with Thomas' wrench. April 24th, foot partially cor-

rected 30 degrees; cavus remaining. July 20th, after six weeks' *redressment*, practised bi-weekly, varus is corrected; cavus still present. Treatment discontinued six weeks on account of an excoriation. September 25th, cavus corrected.

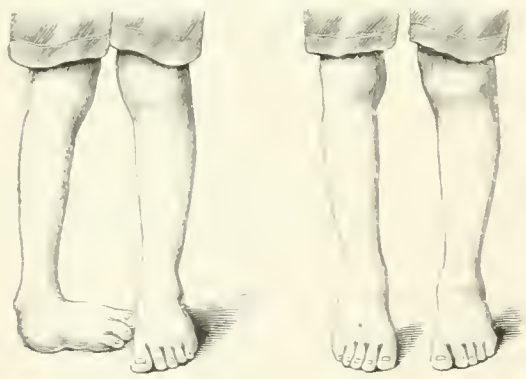
Case III.—W. C., aged eight years. Left equino-varus. Had Phelps' operation in Bellevue in 1891. September 10, 1892, stands with external border of foot on floor, in extreme inversion. March 24, 1893, has had ether five times since admission. The foot twisted with Thomas' wrench and plaster applied each time; 25 degrees of varus still present. Wolff treatment commenced to-day, May 15th, has had *redressment* once a week for past seven weeks. Varus entirely overcome.

Case IV.—Chas. B., aged eight years. Double equino-varus. Left foot has 35 degrees of varus; right 45 degrees. March 21st, etherized; left Achillotomy, plantar fasciotomy, and twisted with Thomas' wrench. Right foot has Wolff method commenced. April 10th, left foot again twisted with Thomas' wrench and put in plaster. April 20th, both feet over-corrected. Right foot has had Wolff method bi-weekly.

Case V.—W. S., aged six years. Left equino-varus 45 degrees inversion. March 25th, Wolff method commenced. June 1st, deformity entirely overcome. Has had *redressment* bi-weekly. Discharged from hospital with foot in plaster and silicate of soda case.

Case VI.—Louis S., aged eight years. Left equino-varus. November 8, 1892, astragalus removed. January 10 and February 20, 1893, under ether; foot twisted with Thomas' wrench. March 14th, Wolff treatment begun; 35 or 40 degrees of varus remaining. April 15th, deformity corrected. Had *redressment* bi-weekly.

Case VII.—R. B., aged 4½ years. Right equino-varus. No previous treatment. August 30th, stand on outer border of foot. Over cuboid bone is callous, size of quarter dollar. Toes point directly across to inner border of opposite



Case VII.

foot. Wolff treatment commenced. October 1st, inversion of foot corrected; had *redressment* tri-weekly; thirteen sittings (see photograph).

Case VIII.—A. T., aged nine years. Left equino-varus. Has had no treatment. Stands on outer border with foot turned to right angle at medio-tarsal joint. September 13th, Wolff

Case VIII.

BEFORE. AFTER.

treatment commenced. October 17th, deformity corrected. *Redressment* tri-weekly for past four weeks (see photograph).

Case IX.—D. P., aged 8½ years. Double equino-varus. Had double Achillotomy when three years old. June 13th, walks on outer border of the feet; toes pointing across to opposite foot; feet are inverted to right angle; has astragalotomy and Phelps' operation on left foot; right foot has Achillotomy, fasciotomy, and twisting with Thomas' wrench. August 9th, 45 degrees inversion of each foot. Wolff treatment commenced on right foot. September 20th, deformity of right foot corrected; eight sittings. October 15th, deformity of left foot corrected in eight sittings.

Case X.—Geo. H., aged twelve years. Talipes equino-varus. Had tendo-Achillis divided when two years old without benefit. November 4th, stands on outer border of foot; weight on cuboid bone, where there is a very large callous, the size of silver dollar; right angle deformity at medio-tarsal joint. April 21st, deformity entirely overcome; weekly *redressment* since admission.

The treatment of these cases necessitated a great amount of patient labor, but one should, I think, feel amply repaid for his trouble when such results can be reached without, in some cases, using either anesthetic or knife; consequently no risk of an operation. The tendency to rapid recurrence in these deformities when left unprotected strengthens the importance of over-correction, and this cannot be too strongly urged. Therefore convert the equino-varus into a calcaneo-valgus and hold it there until this new position becomes permanent. There is no better way of doing this than by the means here advised and its cheapness and efficiency are points which commend it to the profession.

HYPERTROPHIC CIRRHOSIS WITH JAUNDICE.[1]

By JOSEPH EICHBERG, M.D.,
OF CINCINNATI.
PROFESSOR OF THEORY AND PRACTICE, MIAMI MEDICAL COLLEGE; PHYSICIAN TO CINCINNATI HOSPITAL.

The subject which I offer for your deliberation to-night is one of considerable interest to the clinician and pathologist; an interest heightened by the yet debated question of the right of this disease to a name, or to any consideration as an independent affection. For there are those who assert that there is no such thing as hypertrophic cirrhosis, *per se*, and that the clinical and *post-mortem* determination of an enlarged and hardened liver by no means justifies any distinction between this and the common variety of atrophic cirrhosis, of which it is to be regarded as an early stage. Against this view I hope to offer some evidence convincing to me, however it may impress the audience—evidence furnished in part by the liver itself; in part by the brief history of a case; in part by an examination of the literature on the subject.

Originally described as a separate nosologic entity by Todd, it is mainly to the labors of the French school that we owe our recognition of the distinctive clinical and pathologic features of this affection. Charcot and Gombault, Hanot, Tissier, Dieulafoy, Jaccoud and Cornil, with many others who have contributed less prominently, are permanently identified with the graphic, one might almost say classic, descriptions of the disease. In Germany the acceptance of the doctrine of its independent character has found slow progress, and even now the principal opposition to this view is found in the writings of German teachers. In England a number of cases have been reported; comparatively few, however, in this country. On this account and because of a recent opportunity to examine the body of a patient dying from hypertrophic cirrhosis, it has seemed proper to again call attention to the subject.

The history of the case is about as follows:

The patient, a young woman in her twentieth year, of good physical development, and correct habits, noticed, about two years preceding her death, slight jaundice. Accompanying this were the usual gastric disturbances, loss of appetite, anorexia, and weakness, as well as cutaneous itching. The patient continued her work, being employed in a mercantile office, but suffered pretty constantly from the jaundice, which would grow more or less intense, from time to time, without apparent cause. Some time after the onset of the jaundice there occurred severe attacks of epistaxis, in the course of which the loss of blood became very great; so that the anemia added another element to the exhaustion of the patient. There was another rally and then pain and heaviness began to be felt in the right side. Finally came fever, typhoid in character, continuous, with tolerably high range; intense jaundice, the skin assuming that olive green color described by the French as grave icterus; the urine becoming brownish-black, depositing an abundant sediment of urates upon standing, the stools being frequent and of rather darker color than normal; only at rare intervals was a lighter color observed. Both liver and spleen were greatly enlarged. The border of the liver could be easily felt through the relaxed abdominal wall, some three inches below the costal margin in the mammary line. Its upper boundary, determined by physical examination, was found at the lower margin of the fifth rib. The surface of the organ was smooth on palpation, the enlargement apparently uniform, so that the proper relation between right and left lobes was maintained, the edges being sharp and clearly defined, without nodosities or irregularity. The spleen was enlarged to about twice its normal size.

Toward the end, curious nervous symptoms developed. There was aphasia, with partial recovery; slight hemiplegia, delirium, stupor, coma, and death, four days after the sudden aphasia.

A complete autopsy was not permitted, the examination being restricted to the abdominal cavity. The liver, greatly enlarged and of a very dark olive color,[1] projected below the margin of the ribs. Its surface, smooth in appearance at the first view, was found to be slightly uneven, there being a number of minute projections, rather spherical in character.

The enlargement seemed to be uniformly distributed, and the enlarged liver retained its regular outline and proportions. It was very firm to the touch, but was cut without difficulty, though the resistance to the knife was greater than would be encountered in normal liver tissue. The gall-bladder contained an unusual quantity of dark bile, more limpid than normal. Upon opening the duodenum and pressing upon the gall bladder, the biliary passages were found to be free from all obstruction, the bile emerging readily from the papilla of Vater.

The cut surface of the liver was smooth, and presented the same greenish-black hue that had been remarked at the surface. There was no mottling, no variety of color. The tissue throughout presented the same appearance. The spleen was firm, its capsule slightly thickened. The parenchyma was dark in color, dry upon section. A pocket of enlarged lymphatics, slightly red in color, was found behind the portal fissure. Upon microscopic examination the structure of the glands was apparently unaltered.

[1] Read before the Cincinnati Academy of Medicine, October 13, 1895.

[1] Even after hardening in alcohol the liver retained this greenish color, making it look as though it had received preliminary treatment with a chromium solution.

The chief interest centered in the microscopic examination of the enlarged liver. A diagnosis of hypertrophic cirrhosis had been made *ante-mortem*, and the sections presented to-night testify to its correctness. A very full and accurate description of the so-called biliary hypertrophic cirrhosis is given by Hanot and Schachmann, appended to the history of a typical case of the disease observed in the service of Professor Proust. The microscopic details might have been taken from the sections presented for your inspection.

Upon examining the sections with a low power, the most striking and evident change is the enormous increase of the connective tissue. In all directions bands of this new-formed texture traverse the field, now surrounding the lobules entirely, now dipping into the substance of the lobule, to terminate in a roundish, bulbous extremity, like the head of a serpent, as Hanot has it, or sending single filaments across the periphery of the lobule, by which one or two cells are cut off from the rest, to undergo ultimate extinction, an intra-acinous distribution.

With the low power, too, another fact is strongly brought out, namely, the integrity of the secreting structures of the gland proper, of the liver cells. It will rarely happen in a section of perfectly normal liver tissue, taken from a subject dying of disease unconnected with hepatic changes, that the liver cells will be found so little impregnated with fat, so homogenous in their protoplasm, and with nuclei so clearly defined. It is this striking immunity of the liver cells, more perhaps than some of the other details presently to be described, which is specially characteristic of biliary hypertrophic cirrhosis. We shall see that there may be increase of connective tissue from other causes; but in all such instances it will be found that this increase goes hand in hand with degenerative changes of some sort in the liver cells.

Under the low power, the relation of the vessels and ducts can also be seen to be materially changed. The larger trunks of the portal circle, imbedded in the connective tissue separating the lobules, show no very marked changes. Their walls are loosely attached to the new-formed texture, and, while slightly thickened, do not present that degree of infiltration and puckering so evident in the alcoholic variety. The arteries show no special change. It is, however, apparent that the bile ducts have undergone a decided change. When seen in longitudinal section the epithelium is larger, the ducts, crowded with cells, ramify in various directions and their lumen is wider than normal; in cross section, the ducts are found to be surrounded with many concentric layers of new-formed connective tissue far exceeding in thickness the coats of either vein or artery, and often that of the calibre of the involved duct itself. In many localities the tissue immediately surrounding the ducts is the seat of a round-celled proliferation, indicating probably the earliest stage in the process of connective tissue overgrowth.

The capsule of the liver shows no special thickening, but very gentle depressions occur at the boundaries of subjacent lobules, where strands of connective tissue find attachment to the capsule.

With the high power, the characteristics just referred to can be more readily distinguished. The liver cells, with sharply defined outlines, clear, distinct nucleus and homogenous protoplasm, are, perhaps, even of slightly larger dimensions than in the normal liver. Hanot claims that this is the rule in biliary hypertrophic cirrhosis; the point is disputed by Ackermann and others. Whether enlarged or not, it is very evident, with the greater magnifications, that they have, for the most part, remained unscathed by the pathological process around them. They extend to the very edge of the interlobular connective tissue growth, and it is only at the boundaries of the lobule that they may occasionally be seen, slightly flattened and misshapen, less deeply tinged with the staining fluid, and with a faintly outlined nucleus. The normal arrangement of the cells in columns has also been preserved. Here and there, instead of distinct lobules, small groups of cells, ranging from two upward, will be found imbedded in a dense overgrowth of connective tissue. These have been cut off from some neighboring lobule by the shoots of new tissue that grow into the lobules from the periphery, finally reaching across the lobule, so that these become segmented. It is this subdivision of some of the lobules into smaller aggregations of cells that explains the difficulty of locating the hepatic radicle, which, when present, is found to preserve its normal relation to the surrounding liver cells, its walls showing no thickening.

The connective tissue, while not peculiar, is still very different in appearance from that observed in other forms of cirrhosis. It has been compared by Brissaud to the peculiar spongy, neuroglia-like product that is seen in the brain and cord in disseminated sclerosis. It has comparatively little tendency to fibrillation; its spindle cells retain their contour, without elongation; and the greater portion of it, as seen in its more recent stages, dipping into the lobules, consists of a faintly granular homogenous structure, having no sign of organization. It is probably this peculiarity which explains the integrity of the liver cells. The new growth, soft and spongy, insinuates itself between the lobules, or, it may be, between the cells, merely crowding them aside to make room for itself, but not otherwise exercising much pressure upon them, its growth being so gradual that the capsule is slowly distended, and the nutrition of the cells unimpaired. The round-celled infiltration, already alluded to, is found with the high power to consist of young cells, staining readily, and arranged particularly around the biliary ducts, as though the irritation leading to the new formation had started there. The epithelium of the ducts remains unchanged; its distinctively cylindrical character is plainly evident, the calibre of

the ducts is sometimes open, sometimes crowded with cells as from a catarrhal proliferation. Nowhere is there any evidence of biliary pigmentation or obstruction, such as can be seen in another specimen which I present. A number of small secondary biliary vessels of new formation are also seen in the connective tissue; and the columns of liver cells are separated in places by spaces corresponding to the dilated biliary radicles.

With these lesions and these symptoms, can we substantiate the claim of biliary hypertrophic cirrhosis to be regarded as an independent disease? Most assuredly. Clinically we have the following facts:

1. The tender age of the patient. From an examination of the literature of the subject, consisting for the most part of case reports, with occasional account of a microscopic examination, it will be seen that nearly all cases belonging strictly to this category are under 40 years of age, the majority below 30. The two sexes appear to suffer in nearly equal ratio. Children are not exempt. Thus, Smith[1] reports a case in a child of 4½, without hereditary history of syphilis or alcoholism; Florrand,[2] case in man aged 19; White,[3] case in child aged 9, the liver weighing 41 oz.

Hatfield[4] reports a case in a new-born infant.

2. The long duration of the illness. There is the history of suffering, extending as a rule over several years. In the case from which the sections are taken, symptoms referable to the liver disease occurred at least four years before death. The average duration is given at from two to four years.

3. The early occurrence of jaundice, with gradual increase in the intensity of the bile staining, and death at the close of profound nervous disturbances, generally attributed to cholemia. The jaundice may be so slight as to attract but little attention at first; it may lead to pruritus, more or less intense; there may be exacerbations and remissions, but it rarely disappears entirely, even for a short period. With the jaundice—and this point deserves special emphasis—there is diarrhea (from four to eight stools in the twenty-four hours), the stools being liquid or mushy, and either of the normal color or of a deeper brown, showing that bile freely enters the intestine. The patency of all the biliary passages, and the fact that the gall-bladder is generally found to contain more than the usual quantity of bile at the autopsy, plainly shows that the jaundice is not obstructive in origin, as was once asserted.[1]

It is to be remembered that jaundice is an occasional manifestation in the course of atrophic cirrhosis; but the fact that Mangelsdorf, quoted by Freyhan, in trying to make this symptom wholly lacking in diagnostic significance, was able to collect in the whole literature of the subject only eight cases of atrophic cirrhosis with jaundice, goes further than all else to show its very exceptional appearance in that disease.

4. The absence throughout the entire affection of the usual signs of portal obstruction. There is, in the history of the disease, neither the enlargement of the superficial abdominal veins, the formation of the so-called caput medusæ, nor ascites; and though it should appear from an examination of the specimens in our own case that the portal vessels imbedded in this immense overgrowth of new-formed connective tissue must have their walls compressed, the circulation goes on without evidence of impediment; so that Ackermann was able to inject the liver from the portal vein, the fluid, tinged with Prussian blue, passing freely into the hepatic radicles in all parts of the liver substance.

5. The occurrence of severe hemorrhages from the mucous surfaces at a comparatively early period. Epistaxis, so severe as to be alarming, occurred several times in the case here reported. A similar fact has been noted in others. Hematemesis, melena, bloody urine, and vaginal hemorrhages have been reported.

6. The development of febrile attacks, of variable duration, resembling in type either remittent or typhoid. This feature is not invariably associated with the disease, but is by no means uncommon. When fever develops and is associated with pain and gradual enlargement, it is easy to mistake the condition for hepatic abscess. Jaccoud and Molénes report cases occurring in their respective practices in which this mistake was made, and the supposed abscess repeatedly aspirated, the needle only withdrawing blood.

7. The tendency to progressive and extreme enlargement of the liver, with pain in the right hypochrondrium, fulness and weight, and manifest increase in the circumference of the abdomen, just below the costal margin. As a concomitant of the hepatic enlargement, the spleen is also increased in size. The hepatic enlarge-

[1] *Trans. Path. Soc. Lond.*, Vol. XLI.
[2] *Progrès Med.*, 1885.
[3] *Path. Soc.*, Vol. XXXVI.
[4] *Trans. Am. Pediatric Society.*

[1] Musser (*Am. Jour. Med. Science*, 1884) is, I think, in error in stating that the term *biliary* is applied to these cases because of obstruction of the duct

ment, while generally uniform, may involve one or other lobe in preponderating degree. The weight of the organ many reach nine pounds and over.

8. The inevitable tendency to a fatal termination.

9. The inability to refer the development of the disease to alcoholic excess, in all but a small proportion of properly classified cases. I am aware that upon this point issue is likely to be taken, yet an examination of cases hitherto assigned to this category will convince any impartial critic of the correctness of the statement. It will be seen that many cases occurring in patients addicted to alcoholic excess, designated as hypertrophic cirrhosis, have either presented ascites and other evidences of portal obstruction during life, or have shown, after autopsy, under the microscope, very advanced fatty changes in the liver cells. It will also appear that in nearly every instance the age of the patient has been 50 or above in male patients, though females seem to suffer at an earlier age from the effects of alcoholic excess, as regards hepatic enlargement.

Now, the term cirrhosis was originally introduced by Laennec merely to designate a peculiar color change in the liver. It has received wider application in that it has been used to designate not only those conditions of the liver characterized by connective tissue overgrowth, but is employed as a generic term to denote a pathologic process in which this proliferation is the main feature, so that we speak of cirrhosis of the kidney, of the lungs, of the pancreas, etc. If then, all cases in which, with the new development of connective tissue, there is increase of size in the liver shall be termed hypertrophic cirrhosis it will become necessary to employ a second qualifying adjective to indicate more clearly the nature of the enlargement. For increase of connective tissue, with hepatic enlargement, occurs under divers conditions, so that we have a hypertrophic cirrhosis from venous engorgement in cases of valvular disease of the heart, the nutmeg liver; from syphilis; from malaria; from permanent obstructions of the common duct, as by the impaction of a gall-stone, or by cancer of the head of the pancreas; from fatty change with cirrhosis, as the result of chronic alcoholism, and from diabetes. I am fortunately in position to show you examples, under the microscopes set up in the adjoining room, of the histological changes wrought by each of these different causal elements in the liver tissue, in contrast with the changes of so-called biliary hypertrophic cirrhosis.

The nutmeg liver shows the new growth plainly radiating from the hepatic radicle, the portal vessels and gall ducts being perfectly free, the liver cells, however, undergoing some degeneration, the walls of the hepatic vessels being greatly thickened. The syphilitic induration has not the regular distribution of the other forms, but presents a ribbon-like development, in which there may often be found minute gummata; sooner or later there comes, in this form, marked cicatricial depressions and irregularity of the capsular surface. In chronic malaria there is deposit of masses of black pigment between the cells.

In chronic biliary obstruction there is marked irregularity in the size and outline of the liver cells; the nuclei are not clear, the protoplasm stains imperfectly; the minute biliary radicles between the cells are enormously dilated, and filled with inspissated bile, which appears on the sections as patches of a greenish or brownish color. The bile ducts are surrounded by some new formed tissue which has neither the regular distribution nor the bulk of the connective tissue in the disease we are studying. I would call attention to this fact particularly, since Charcot, influenced by what he observed as the result of ligature of the common duct in the lower animals, proposed for this affection the name of biliary hypertrophic cirrhosis, a name that we still retain, though it does not in any way fit the pathology, seeing that the larger bile ducts are always open.

The cirrhotic liver with fatty degeneration shows such a degree of fatty change in the liver cells that its recognition requires no further explanation. In diabetes, Hanot and Chaufford noted the rare occurrence of hypertrophic cirrhosis, with pigmentation of the liver cells; as yet, but six cases of this variety have been reported.

Hanot, Sabourin, and others have given to some of these varieties a special name, which I think it would be well to retain in future description. Thus we may designate—

As biliary hypertrophic cirrhosis, the affection we study to-night;

As syphilitic hypertrophic cirrhosis, the cases due to this specific poison;

As obstructive hypertrophic cirrhosis, the cases resulting from closure of the duct;

As fatty hypertrophic cirrhosis, the enlargement due to chronic alcoholism;

As pigmentary hypertrophic cirrhosis, the cases occurring in diabetic patients;

As congestive hypertrophic cirrhosis, the cases resulting from heart disease, the nutmeg liver;

As malarial hypertrophic cirrhosis, the cases due to chronic malarial poisoning.

The recognition of the particular variety present in any given instance has a manifest bearing on prognosis and treatment.

Up to this time the treatment in all cases of biliary hypertrophic cirrhosis has been unsatisfactory; but the results obtained in the fatty hypertrophic cirrhosis with calomel, given according to the plan of Saccharjin, would certainly justify its employment in this affection, however different the two processes are in point of causation.

A final word as to the pathology of the disease. It seems clear, from an inspection of the specimens, that the essential feature is primarily an inflammation in and about the biliary ducts, angio-cholitis, and peri-angio-cholitis. What determines this is not yet clear. Vincenzi's theory of a micro-organism wholly lacks corroboration; but once begun, the process goes on within and outside of the biliary vessels, leading to cellular proliferation and partial or complete blocking within; to formation of a young and rapidly growing connective tissue without the ducts. The circulation meanwhile is unimpaired, so that, with the proper advent of blood, and with perfect integrity of the secreting cells, bile continues to be freely formed. It may be formed in excess, as Ackermann believes, in consequence of the irritative process in and about the hepatic lobules. The blocking of some of the minute ducts offers obstruction to its passage; the patency of others permits the outflow of a sufficient amount to distend the gall-bladder, and give to the feces their normal color. Where the ducts are blocked, resorption of the excreted bile occurs, leading to jaundice, and finally to cholemia. This is the theory of Charcot, essentially modified in detail by Ackermann, whose views upon the subject seem to fit the case more nearly than any other explanation offered up to this time.

I would refer once again to the fact that biliary hypertrophic cirrhosis cannot be considered as, in any sense, connected with the ordinary atrophic variety; that it differs in important particulars from other forms of hepatic enlargement, due to connective tissue growth; and that by every right of etiology, pathological anatomy, and symptomatology it must be conceded a position in our nosology.

CLINICAL LECTURE.

TRAUMATIC CATARACT.

By S. D. RISLEY, M.D.,
of Philadelphia.

When I had the pleasure of meeting you last, I presented for your study the more common forms of cataract. These, we saw, were the soft and hard cataracts, the former occurring in early life for the reason that the lens was then elastic and soft. With increasing years it increases in density, loses the power of changing its form, as it is able to do in youth, and becomes hard. But this we saw was a physiological process and had no necessary relation to loss of transparency, but that when opacity did occur from any reason the result was a hard cataract. I further urged upon you the fact that opacity of the crystalline lens is not necessarily a concomitant of old age, and should not therefore be classified as senile cataract. Common observation shows that even in advanced age, cataract is the exception, so that we are driven to conclude that when it does occur there must be some special cause for its occurrence. This, I told you, would be discovered in the impairment of the nutrition of the lens by disease of the intra-ocular tunics, usually affections of the choroidal tract, either of purely local origin, as in cases of choroidal disease due to eye strain, exposure to heat, etc., or associated with some general dyscrasia.

To-day I wish to bring before you a group of cases

[1] Delivered at the Philadelphia Polyclinic College for Graduates in Medicine, February 28, 1896.

which will serve as a text for the study of traumatic cataract.

Opacity of the lens due to injury may, for purpose of study, be placed in two groups. First, those which have been caused by penetrating wounds; and second, by blows which have caused the rupture of the lens capsule and its suspensary ligament.

It is well known that whenever the aqueous humor is allowed to come in direct contact with the lens cortex that it first causes it to swell, then to become opaque, and finally has the property of dissolving it, after which it is carried off through the filtration channels and absorbents. The surgeon frequently takes advantage of this fact in his treatment of the soft cataracts of youth and early middle life. Now any injury, therefore, which rends the delicate capsule of the lens, causes it to become cataractous, and if the rent is sufficiently extensive, may bring about the absorption of the entire lens. It not infrequently happens, however, that the opening speedily closes after admitting sufficient aqueous to render it wholly or partially opaque, but not sufficient to cause its solution, leaving a permanently opaque lens—a traumatic cataract. Those opacities of the lens, caused by penetrating wounds, may be placed in two classes: first, those due to some sharp instrument, which is subsequently withdrawn; and second, those produced by small particles which penetrate the lens and remain within the eye. I have seen examples of the first class produced by a shoemaker's awl, the point of a penknife, a sharp tack, and you will recall the case of the blacksmith who was discharged from the hospital two weeks ago who had a traumatic cataract, produced by the flying point of a horseshoe nail. A fork tine is frequently the penetrating instrument.

Fragments of iron or steel from the head of a hammer or cold-chisel, fragments of gun-cap, grains of powder, etc., not infrequently enter the cornea and penetrate the capsule of the lens, burying themselves deeply in its substance where they may become encapsuled and remain for an indefinite time; or, passing directly through, may find lodgment within the vitreous chamber. The aqueous is admitted to the lens substance and causes partial or complete opacity, and a corresponding impairment of vision. But these accidents introduce other elements of danger which may prove far more serious than the opacity of the lens. If the foreign body passes into the vitreous chamber and rests upon some portion of the uvea, but especially if it is lodged in the ciliary region, sympathetic irritation is liable to occur and may necessitate the excision of the fellow eye. If the foreign body is copper or brass, although they may be sterile at the time of entrance, as would be the case with a fragment of gun-cap, they nevertheless seem to exert, as has been shown by Leber, an especially baneful influence over the eye, probably through the irritating salts which are formed through their chemical decomposition. Then it must always be remembered that the penetrating instrument, or the entering foreign body, may carry into the interior of the eye micro-organisms which may lead to its speedy destruction by suppurative panophthalmitis, or, even a fatal involvement of the fellow eye. If the cataract has been caused by a blow sufficiently severe to have ruptured the lens capsule and the suspensary ligament, it should be born in mind that it is probable that deeper injury has also been produced. Ruptures of the choroid and retina, and retinal detachments, are by no means rare as the result of blows. A blow with the fist, a baseball, or even the small ball of putty blown from a boy's "blow-gun," may cause not only a traumatic cataract, but as I have several times seen, may cause serious injuries at a point in the deeper tunics at the opposite pole of the eye, usually in the region of the posterior pole. This possibility should be kept in mind and will always suggest a guarded prognosis in these patients, with opacity of the lens following blows upon the eye.

Dismissing these considerations, however, thus briefly, I wish to call your especial attention to a danger often present in these cases, but of an entirely different character. If the rent in the capsule is large, the lens may swell so rapidly under the action of the aqueous humor as to cause a transient glaucoma by pressing the iris forward into the angle of the anterior chamber. By this means the spaces of Fontana are closed, the excretion of intra-ocular fluids impeded or prevented, and thus an increase of intra-ocular tension produced. Or it may be that the increase in the volume of the lens is a factor in the increased tension.

The opacity of the lens produced by injury is often only partial. Small particles of various kinds penetrate the cornea, and their weight or their momentum may be sufficient only to bury them superficially in the lens cortex. Here they are surrounded by a small opaque area, which may remain to the more or less serious and permanent impairment of vision. Or the substance may pass through the iris and enter the lens at its periphery, causing a partial opacity, which may encroach but slightly, if at all, upon the area of the pupil. I recall the case of a gentleman who received such an injury from a small piece of the surface of a glazed brick at which he was firing with his rifle. I watched this for several years, the fragment remaining encysted in the periphery of the lens and causing very little impairment of vision. Grains of powder thrown into the eyes by the premature explosion of blasts in mines and quarries, is a very frequent cause of traumatic cataract. The man, upon whom you witnessed the operation of iridectomy at the clinic yesterday, was an illustration of this class of injury. In that case the iridectomy was preliminary to an attempt to extract the opaque lens.

In the treatment of traumatic cataract, one is often at a loss as to the safest procedure to adopt. In cases of transient glaucoma, where the swelling of the lens is the result of a penetrating wound by some sharp instrument which has been withdrawn, the problem is comparatively simple. A section of the cornea can be made, and a portion of the lens removed, with or without an iridectomy, but when the foreign body is imbedded in the lens substance, the dangers are greater. There is always danger of the foreign body escaping from its bed and falling back into the eye upon the ciliary body. This is of course a most serious accident. If the foreign body is causing no trouble, and if the fellow eye is good, it is

usually best to let it alone, since your most successful endeavor cannot restore binocular vision. Other considerations should however guide you in some cases. In one of the group before you the cataract was produced by an injury with a baseball. As you see, he has a white lens which has been partially absorbed. He has been under observation for many months with recurring attacks of ciliary injection and tenderness. These have become less frequent and severe. His occupation leads him into danger from injury because of his one-sided blindness. I have therefore advised him, when his eye is free from the recurring attacks of inflammation, to have the lens removed. While the operation may not secure perfect binocular vision, it will nevertheless give him sufficient vision on the side of the injured eye to avoid approaching teams and other sources of danger.

CLINICAL MEMORANDA.

DUPLEX PERSONALITY.—REPORT OF A CASE.[1]

By WILLIAM FRANCIS DREWRY, M.D.,
OF PETERSBURG, VA.;
FIRST ASSISTANT PHYSICIAN CENTRAL STATE HOSPITAL FOR THE INSANE; VICE-CHAIRMAN DEPARTMENT OF INSANITY AND MENTAL MEDICINE, MEDICO-LEGAL CONGRESS.

DUPLEX personality is a psychical condition which did not, till recently, attract very much attention; but since brain function and brain action have begun to be more deeply and more thoroughly studied, it has been brought forward as a subject worthy the consideration of the profoundest thinkers. Several valuable contributions relating to diseases of personality, as they are called, have recently appeared. The greater portion of the literature comes from the French, but this country is by no means without its students and investigators in this field of science. Dr. Hodgson, of Boston, Secretary of the American Branch of the Society for Psychical Research; Dr. R. Osgood Mason, of New York; Dr. A. E. Osborne, of California; Dr. Irving C. Rosse, of Washington, D. C.; Dr. Weir Mitchell, and others have each reported interesting cases of duplex or of triple personality, or of periodic amnesia.

The Society for Psychical Research and many eminent psychologists are making studious efforts to understand and to explain the strange mental phenomena exhibited in this class of cases, but no one has yet been able to give a clear, comprehensive explanation of them. However, authenticated data, facts regarding cases, etc., are being accumulated and studied, which, in time, will doubtless lead to a scientific elucidation of the psychological forces involved in duplex individuality, temporary extinction of memory of the past, and allied conditions.

What is understood by that remarkable abnormality, known as duplex personality, is that there is a second and distinct consciousness or individuality entirely different from the original or primary one—that there are two more or less complete phases of existence. In this state of abnormal mentality, mental activity is not suspended. The actions of the mind, however, are in the nature of automatic operations; there is a sort of "reflex activity of the cerebrum."

It has been demonstrated that by the means of hypnotism this second personality, with its added powers of perception, may be brought into action and all the incidents which occurred during that period, clearly related.[1] Somnambulism and some dream states might be considered typical examples of another personality—double consciousness—somewhat analogous to the psychic condition existing in this class.

A remarkable "dislocation of memory," to use the term suggested by Sir H. Holland, occurred once with Sir Walter Scott.[2] He dictated, during a prolonged illness, to his amanuensis the whole of the "Legend of Montrose," almost the whole of "Ivanhoe," and the greater portion of the "Bride of Lammermoor," while in a state of "second consciousness." When the works were finished and handed him "he did not recollect one single incident, character, or conversation." The "original incidents" had not been erased from his memory, "but he did not recollect a single character woven by the romancer, nor one of the many scenes and points of humor, nor anything with which he was himself connected, as the writer."

The counterpart of this strange mental condition is sometimes observed in certain delusional insanities; temporary suspension of consciousness may be caused by certain drugs, hysteria, epilepsy, or other diseases, toxic elements in the blood, change in functions of the circulation and of nutrition, traumatic or organic lesions of the brain-substance or of the nerve-cells, etc.

The following case, the history and details of which were kindly given me by an eminent practitioner, Dr. H. G. Leigh, Sr., of Petersburg, Va., came under my observation within the past year:

Mr. K. was fifty years old, of splendid physique, in good health, in fairly comfortable circumstances, and doing a prosperous business. He was sober, moral, and industrious, of affable disposition, popular with a large circle of friends, member of several secret and benevolent orders, happy and content in his domestic relations. He was born and reared in Virginia, had resided and conducted business in ——— for twenty years or more, and deservedly bore the reputation of being a correct, straightforward man in every particular. For years he had been one of the town officials.

One of his near relatives (an uncle, I think) at about the age of fifty, without any apparent reason whatever, went suddenly out West, leaving his wife and children, and was not heard of for many years. Finally he came back on a visit and remained a short time with his family and old acquaintances, but no explanation was given of his strange conduct. It was thought that he had some form of mental disease.

[1] Abstract of a paper presented at the Medico-Legal Congress, held in New York, September 4–6, 1895. From advanced sheets *Medico-Legal Journal* and the *Bulletin of the Congress*.

[1] Refer particularly to case reported by Richard Hodgson in "Proceedings of the Society for Psychical Research," Part XIX, and to Dr. R. Osgood Mason's paper on "Duplex Personality; its Relation to Hypnotism and to Lucidity," *Journal of the American Medical Association*, November, 30, 1895.

[2] In Carpenter's Mental Philosophy, pages 139 and 444, quoted from Lockhart's Life of Scott. Chap. XLIV.

One day, while apparently in perfect health, without any premonitory symptoms of mental derangement, Mr. K. went to a Northern city to purchase goods for his store. While there two days he transacted a great deal of business, met many old friends, and exhibited no indication of aberration of mind. Starting homeward, he registered as a passenger on a certain steamer; feeling very tired, he secured a stateroom, to which he at once repaired, changed his linen, etc. When tickets were collected he was missing. He had *suddenly and mysteriously disappeared*. No one had seen him leave the boat, jump, or fall overboard. An acquaintance, however, said that he was reasonably certain that he saw Mr. K., several hours after the boat had left, in one of the depots in the city. He was sitting down, hat pulled over his face, and seemed to be in a "deep study," so he was not disturbed. Mr. K.'s open valise and all his clothes, except those he wore, were found in his stateroom. The room door was open, but the key had been taken away. Unusual prominence was given the matter in the public press, and various explanations were suggested during the vain search that followed, until finally investigation was abandoned, the theory that he was dead accepted, and the Court appointed an administrator of his estate, and a guardian for his children. His business was purchased by his son, and everything was moving along smoothly when, *six months after* he was last heard of, he suddenly and unexpectedly appeared at the home of a relative in a distant Southern city. He was brought home in a composed, but partially dazed condition, able to recognize but few of his friends. He was an entirely changed man; the physical and psychical metamorphoses were quite complete. He had reduced in weight from 250 to 150 pounds, and was very feeble. He wore the same suit of clothes he had on at the time he disappeared, and had in his pocket the check and key which were given him on the boat.

He was at once put under treatment, and within four weeks recovered his previous bodily and mental health, and has since conducted his old business with his accustomed skill and industry. A day or two after his return home an abscess, deep down in the auditory canal, broke and discharged a large quantity of sanguino-purulent matter. *Immediately thereupon improvement began*, and went on rapidly. This was a remarkable fact, and is, I think, worthy of special note.

Hear Mr. K.'s own account of his strange case: "I was feeling very tired, thoroughly fatigued, after a very busy day in the city, so went to my stateroom immediately upon going aboard the boat, and changed my clothes. Up to that time I was thoroughly conscious, but *after that I recall nothing, all was oblivion till six months later*, when I came suddenly to myself in a distant city in the South, where I knew no one. I found myself driving a fruit wagon on the street. I was utterly astounded. Why I was there, how I got there, when I came, what I had been doing, were puzzling questions to me. Upon inquiry, I learned that I had been there and at work for some time. My life, since I was in that stateroom, six months previously, had been an absolute blank to me. I can give no account of myself during that period of time. *I recall nothing*.

"I started at once for Virginia, but on the way I again lost consciousness, though for only a day or two. When further on the way home I felt so utterly worn out, I stopped in a certain town and went to the house of a near relative. From there I was taken home. I was in a half-dazed, confused condition, and remained so some days longer. I am now feeling well and all right."

He could not tell where he had lived in that Southern city, or the name of any person he had known there. He was, indeed, a stranger in a strange land. Nothing definite has been ascertained regarding his life during his *second consciousness*.

This case bears many striking resemblances to others that have been from time to time reported, but there are two points of special interest. First, the *inherited tendency* to *eccentricity*, if not to *insanity*. Second, *the abscess in the ear*, the breaking of which was followed by a rapid return to normal mentality.

[Nearly a year has elapsed since recovery and no relapse has occurred; on the contrary, Mr. K. has enjoyed excellent health, mentally and physically, and is now doing a good mercantile business at his old stand.]

RECTAL GONORRHŒA AND GONORRHŒAL ENDOMETRITIS.

BY JOHN J. ORTON, M.D.,
OF RANDOLPH, O.

WHEN I read Dr. Murray's article on "Gonorrhœa of the Rectum" in THE NEWS of March 7th, it occurred to me that a report of a similar case, which has recently been under my care, might be of interest to the profession.

On November 12, 1895, I was called to visit Mrs. ——, aged forty, mother of two children, the youngest of which is fourteen years of age. Her previous health

had been quite good, except that she suffered at times with indigestion. For several days previous to my visit she had been suffering with the usual symptoms of acute vulvitis, for which her husband had consulted me at my office and obtained medicine. He also told me that she had a swelling of one of the labia. Examination revealed a fully developed vulvo-vaginal abcess, vulvitis, and urethritis. Vaginitis was also suspected but, as the parts were so sensitive on account of the abcess, no attempt was made to pass the speculum. I opened the abscess, evacuated the pus, and ordered the treatment continued that I had prescribed when consulted at the office, which consisted of lead and opium lotions for the vulvitis, hot poultices to the abscess, and vaginal injections of warm water containing a solution of lead acetate. A day or two later I was able to pass the speculum and found, as I expected, a vaginitis. The appearance of the os uteri looked as though the woman had been suffering with a chronic erosion of the cervix before her attack of the gonorrhœa.

There was no question as to diagnosis, as the husband admitted that he was having an attack of gonorrhœa.

The usual remedies were used with good success in curing the vulvitis, urethritis, and vaginitis, but other complications developed which taxed my skill. In spite of the best treatment with which I was familiar, either by experience or reading, cervical endometritis developed, which gradually crept onward until it invaded the uterine cavity, and I had to deal with a corporal endometritis of gonorrhœal origin. The patient had complained of pain and an uneasy feeling in the rectum, which I supposed was caused by internal hemorrhoids. One morning while using Sims' speculum, during the treatment of the vaginal and uterine trouble, I was amazed to see about a teaspoonful of muco-pus ooze out of the anus when I depressed the perineum with the speculum. It immediately dawned upon my mind that my patient was suffering with gonorrhœa of the rectum in addition to that of her genital organs. In fact, everything possible was infected except the tubes and the bladder and the parts beyond them. Unless vigorous treatment was used it would probably be only a matter of time until pus-tubes would be added to the already serious condition of my patient. She was then suffering severely with uterine cramps, and bimanual palpation showed the uterus to be sensitive and tender.

On January 14, 1896, Dr. C. S. Hiddleson administered chloroform, and while she was under the anesthetic I first cleansed the vagina and vulva with an antiseptic solution and irrigated the uterine cavity with H_2O_2, one part to boiled water, three parts to wash away the purulent discharge. I then thoroughly curetted the uterine cavity and cervical canal with a sharp curette, irrigated again with plain boiled water, applied equal parts of pure carbolic acid and tincture of iodin to the endometrium and cervical canal, and finished by packing the uterus and vagina lightly with iodoform gauze. The patient rapidly improved from that time on, but some cervical catarrh remained which eventually responded to treatment.

The rectal trouble was treated first with injections three or four times a day of H_2O_2, one part to water, three parts containing sulpho-carbolate of zinc, five grains to the ounce. This seemed to do good until, on December 29th, she was seized with a constant desire to go to stool and passed blood, mucus and shreds of mucous membrane. I then changed the rectal treatment to injections of creolin one-half to three-fourths teaspoonful to a pint and a half of warm water every six to eight hours, alternating with fl. ext. hamamelis, four to six drams to water, a pint and a half. This proved efficient and the rectal difficulty gradually subsided. The injections were reduced in frequency as improvement progressed, and finally omitted, but, as she had a slight return of the trouble, they were again resumed with good results.

Like Dr. Murray, I found no help from text-books in treating the rectal complication. Rectal gonorrhœa is not mentioned in any text-book I have consulted, and Dr. Murray's article is the first I have ever seen on that subject.

To explain how the rectum became infected in my patient is difficult. My theory is that the discharge from the vagina running down over the anus was the cause, or else a little of this discharge was introduced into the rectum by using an enema to move the bowels, although a different nozzle was employed for this.

MEDICAL PROGRESS.

The Action of Erysipelas on Syphilis.—According to the *British Medical Journal* for February 29th, RUDOLPH, in *Centralbl. f. inn. Med.*, February 1, 1896, relates two cases with syphilitic manifestations in which an accidental erysipelas occurred. A man, aged fifty-two, had two syphilitic ulcers on the face. The erysipelas affected both sides of the face. Five days after the defervescence, and nine days after the onset of the erysipelas, the ulcers were healed.

A woman, aged twenty-five, contracted syphilis five years previously. She now had severe headaches, and paresis of the left side of the face, with occasional clonic spasm. In addition there were enlarged submaxillary glands, and a chronic arthritis affecting both knees. Syphilitic cachexia was marked. She had been through several courses of antisyphilitic treatment, including mercurial injections and inunction. After an attack of erysipelas the patient was cured of her chronic syphilis. The glands went down, the pains in the head and joints disappeared, and the facial paralysis gradually recovered. For a year she remained free of any syphilitic manifestations, when a gumma appeared in the leg. The patient would not submit to further antisyphilitic treatment. The rapid and beneficial effect brought about by the erysipelas in these cases was striking. Unfortunately the first case was not seen again, and so it could not be stated whether he remained free of relapse. In the second case the cure was not permanent, but the erysipelas had more effect on the disease than the antisyphilitic treatment.

Practical Value of Roentgen Photography (Skiagraphy).—As an illustration of the diagnostic possibilities of the Rontgen light in surgical practice, Professor König, of

Berlin, at a recent meeting of the Berlin Medical Society (*Deutsche medicinische Wochenschrift*, 1896, No. 8, p. 113), related the case of a woman, forty-six years old, who several years previously suffered from a painful swelling of both knee-joints, which moderated upon the right side and soon disappeared upon the left. The tibial portion of the right knee-joint, however, in a short time began to swell: the joint became mobile in a lateral direction, and walking was rendered impossible. On examination the right leg was found greatly atrophied, and the knee-joint empty. The tibial portion of the joint, however, was enlarged and in circular form. The diagnosis between inflammatory disease of the tibia and a neoplasm was decided in favor of the latter from the presence of pulsation in the softened anterior portion of the tibia. Ablation of the femur was decided upon and effected. Attempts had been made to utilize the Rontgen light, but were successful only after the operation had been performed. Examination of the specimen showed the joint to contain no fluid, but presenting evidences of the existence of a previous sero-fibrinous inflammation. Sagittal section of the tibia disclosed the presence of a spindle-cell sarcoma, involving the epiphysis and the upper part of the shaft. A shadow-picture, prepared from the lateral aspect of the joint, showed the inner condyle of the femur, the inter-articular fibro-cartilage, and the upper margin of the tibia. Below the last could be seen the shadow of a peculiarly lobulated tumor of lighter shade than the surrounding bone. The lower boundary of the tumor gradually merged into the shaft of the tibia. The condyles of the femur appeared on superficial examination of normal configuration, but a skiagraph from the lateral aspect disclosed the presence, in the epicondyle, of a small body of dark contour, which upon subsequent section of the bone proved to be an enchondroma of the spongy portion of the epiphysis.

In the same journal containing the report of Konig, a case is detailed by Hammer (*Ibid.*, p. 114) in which a soldier believed that he had accidentally introduced a needle into his hand, but beyond a punctured wound no trace of the foreign body, in whole or in part, could be detected. Upon exposure of the member, however, to the Rontgen light a fragment of the needle was readily demonstrated at some distance from the wound of entrance, and was subsequently excised with especial facility.

Prognostic Significance of Albuminuric Retinitis.—E. Oliver Belt, M.D., Washington, D. C. (*Journal of Am. Med. Ass'n.*, November 2, 1895). The writer collected the records of 419 cases of albuminuric retinitis from ophthalmologists throughout the country: "The time allowed was too short for many to look over their records, and many had not kept trace of the patients after referring them back to the family physician, but enough cases were reported to show that the duration of life is longer among private patients, and that renal affection is immediately influenced by hygienic surroundings. However, the number of cases surviving two years was disappointingly low, and the consensus of opinion seems to be that nearly all prove fatal in less than two years.

"From all the statistics I have been able to find we get the following results: Cases in private practice, 155; of these 62 per cent. died within one year, 85 per cent. within two years, and 14 per cent. lived more than two years.

"Hospital cases, 77; of these 85 per cent. died within one year, 93 per cent. within two years, and 6 per cent. lived more than two years.

"Mixed cases, 187; of these 65 per cent. died within one year, 93 per cent. within two years, and 6 per cent. lived more than two years.

"Total number of cases, 419: of these 72 per cent. died within one year, 90 per cent. within two years, and 9 per cent. lived more than two years."

THERAPEUTIC NOTES.

Argonin is described as a combination of silver and casein, existing as a white powder, which Lewin (*Berliner klinische Wochenschrift*, 1896, No. 7, p. 146) has employed in the treatment of acute gonorrhœa, using a solution of 3 parts to 200 of water, and making an injection of 2½ fluid drams five times daily. The results were entirely satisfactory, the medicament exerting a destructive influence upon the gonococci and being free from irritating properties, although it was wanting in astringent qualities and thus was unable to control existing inflammation of the urethral mucous membrane.

The Treatment of Typhoid Fever with Antitoxic Serum.—Borger (*Deutsche medicinische Wochenschrift*, 1896, No. 9, p. 132) has employed antitoxic serum obtained from the calf in the treatment of twelve cases of typhoid fever, with results that for the present must be considered uncertain. In four cases it is thought that the serum may have exerted a favorable influence, but the most that can be said with certainty is that the injection of large doses of the serum is unattended with evil results, and that a favorable effect upon uncomplicated mild cases of typhoid fever treated early may be anticipated.

For Epilepsy.—

Take of

Codein	℥ j
Potassium bromid	℥ ij
Infusion of adonis vernalis	℥ iv

Mix. Dose: From half a teaspoonful to a teaspoonful thrice daily.—*Gaz. hebd. de Méd. et de Chir.*, 1896, No. 17.

For Burns.—

Take of

Aristol	From a dram to two drams

Dissolve in

Olive oil	Half a fluid ounce

Add

Vaseljn Lanolin } aa	Two drams.

Mix. Apply topically.

—*Gaz. hebd. de Méd. et de Chir.*, 1896, No. 17.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to The Medical News will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 Fifth Avenue (corner of 18th St.), New York.

Subscription Price, including postage in U. S. and Canada.

Per Annum in Advance	$4.00
Single Copies	.10
With The American Journal of the Medical Sciences, Per Annum	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

and Nos. 706, 708 & 710 Sansom St., Philadelphia.

SATURDAY, APRIL 11, 1896.

THE PERSONAL ADVANTAGE IN HIGHER EDUCATION.

Allusion has already been made in these columns to the recent decision of the Faculty of the Harvard Medical School to require candidates for admission after 1901 to present a degree in arts, science, or medicine. Great as is the importance of this step, we can but think that it is somewhat overestimated, in one particular, by our esteemed contemporary the Boston *Medical and Surgical Journal*, which says in a recent issue: "Parents will not be slow to recognize the great prestige that the degree of such a school will give their sons in the outset of their professional career, and many positions will be open to men with this higher Harvard degree to which the graduates of other schools with a lower standard could not aspire."

There is no degree which gives a great prestige to its possessor in the outset of his professional career. The average physician is dependent on the public for his livelihood, and the public cares but little about the school from which he comes while it cares a great deal about the man himself. In general, the physician's success will be in direct proportion to the thoroughness and completeness of his training, but so much depends on the man that one will gain more with small opportunities than will another with great.

Let it be understood that we are far from decrying the step which the Harvard Medical School has taken, or its influence on the profession in general; other schools will follow, and the progress of the leaders will draw in its wake the smaller colleges, and so advance will be made all along the line. Schools increase rather than decrease the number of their students when they advance their requirements and their advantages. The medical schools of New York furnish a marked illustration of this. The more rigorous the course has been made the greater has been the number of students. But we must not be unjust to the smaller schools. Many of them are doing excellent work, work of the most progressive character, and so many factors must be counted upon in determining the prestige with which a young graduate starts in his career that we may not be surprised to find, as we frequently do, that the leader in the race is reflecting honor on a comparatively obscure alma mater.

MEDICAL ARTICLES IN LAY MAGAZINES.

Harper's Magazine for February, 1896, contains a contribution by Dr. Forbes Winslow on "Premonitions of Insanity."

The bad taste or judgment exhibited by the editor or publisher in soliciting or publishing such an article for presentation to the general reader does not concern us, nor will we waste time debating the ethical aspect of the question, as in these days ethics seem thrown to the winds; but the article referred to has a world of mischief in it. In a medical publication it would seem puerile; in a lay periodical it is outrageously harmful.

According to the author, using his own words, "drowsiness," "disturbed sleep," "troublous dreams," "insomnia," "giddiness," "defective memory," "want of energy," "neglect of work," "great difficulty in concentrating thoughts and ideas," or, in "turning or fixing the mind on any one subject," "wandering of mind," "restlessness," "peevishness," "capriciousness," "irritability," "seeking seclusion," "dilated, unequal,

or contracted pupils," etc., etc., are among the *premonitions* of insanity, and nowhere is it said that they, one or all, may be also symptoms of different and, very likely, easily curable affections.

The danger of thus parading before general readers, many of whom are receptive and impressionable, and some of whom are already morbid and introspective, a lot of symptoms which are possibly due to an indigestion, an anemia or a plethora, a lithemia or an old iritis, as premonitions of insanity, should be obvious to all. The harm such injudicious and misplaced information may do is incalculable. How many will it temporarily rob of peace of mind? How many will it make permanently unhappy and apprehensive? How many will, because of it, brood over some simple ailment until their morbid fears become delusions, their hypochondriasis melancholia? Who, knowing the tendencies of our neurotic age, dare say that scores of cases of mental alienation will not trace their aggravation, nay, very inception, to this piece of impudent folly?

The influence for harm in this article is magnified because its author poses as an expert alienist, and testified as such in a recent homicide trial in this city. Medical experts are in sufficiently bad odor already; but what shall we think of one who publishes broadcast to the world such a statement as this: "There are so many varieties, and so much light and shade to be observed in madness that only an experienced authority can detect the insidious but sure approach of that malady which deprives one of nature's light and reason and reduces him to the level of the beast which perisheth." Thus, after instructing us how to diagnose and perhaps make ourselves insane, he says only an authority can surely detect the truth—and he is an authority!

VENEREAL DISEASES AND SYPHILOLOGY.

NEW THERAPEUTIC METHODS IN SYPHILIS.

Like the hunt for the philosopher's stone and the method of making artificial diamonds, the search for an ideal treatment of syphilis goes merrily on. One reads with amazement the chimerical and even dangerous methods which are gravely advocated for the treatment of this infection, and one marvels at the audacity of some of the claims made for their curative effects. One of the latest fads is to inject solutions of bichloride of mercury directly into the veins, with the idea of producing a certain and rapid result. The vogue of this seemingly dangerous procedure had its origin in certain good results obtained by Bacelli by the intravenous injection of quinin in malaria. This author and Pyle have already written of the benefits to be derived in syphilis by throwing the sublimate solution directly into the veins. Görl gravely informs us (*München. med. Wochenschr.*, No. 20, 1895) that he injects an aqueous solution of bichloride, of strength of 1 to 3 per cent., into veins rendered very visible by ligation or pressure farther up the limb. Before the injection is thrown in, a few drops of blood should be allowed to escape through the hypodermic needle, in order to give the operator confidence. It is said that this little operation is painless and free from danger; that a small dose of the drug only is required, and that the resulting cure is rapidly effected. In some cases the veins are so hidden or so little developed that they do not lend themselves to the treatment, which should be reserved for cases in which a rapidly produced effect is necessary. Bruni (*Il Policlinico*, May 11, 1895) details the case of a young man syphilitic for four years, who suffered from Jacksonian epilepsy, which was not relieved by injections of gray oil and the internal use of iodide of potassium. Three milligrams of sublimate in watery solution were thrown into the left median cephalic vein, and the next day six milligrams were similarly injected. After these two injections the epileptic attacks and the headache ceased, and as a result of the use of sixteen injections the patient was pronounced cured.

Dinkler (*Berl. klin. Wochenschr.*, pp. 382, 410, and 437, 1895) treated nine patients by this method, and he considers it more effective than the usual modes of administering mercury. This author thinks with Bacelli that by intravenous injection the mercurial is brought into immediate contact and acts directly upon the vascular walls, which are so constantly affected by syphilis. This point, in my opinion, is worthy of further thought and study.

Dinkler's results were strikingly good, but he is evidently alive to some of the shortcomings of

this treatment. He also emphasizes the fact that some people have inaccessible veins. In addition to this objection he also mentions thrombosis and embolism. Dinkler thinks with Blaschko that relapses are more to be feared when the intravenous treatment is used than when mercurial inunctions are made, for the reason that the mercurial salt is so rapidly eliminated from the system. Dinkler concludes that, although the treatment is rational, it will never displace the older methods; that it may be employed in cases of lesions having a rapidly destructive course, in many emergencies, and as preliminary to general anti-syphilitic treatment. He thinks that it will prove valuable in some grave cases of cerebral syphilis, and that in desperate cases it may be used in a limited manner simultaneously with mercurial frictions.

Stoukovenkoff (*Meditzin. Obozrenié*, No. 18, 1895) has used intravenous injections of sublimate and benzoate of mercury in thirty cases of early syphilis, and has seen rapid results follow therefrom. He found that the mercurial was excreted by the kidneys and the sudoriparous glands, and that the quantity thus eliminated was in direct proportion to the amount injected. He found that the quantity of mercury necessary to produce a therapeutic effect was as large as when the drug is administered hypodermically. In this view he is not in accord with Bacelli. Stoukovenkoff speaks very significantly of such complications as phlebitis of one or two months' duration, of abscesses and thrombosis, but thinks that with an improved technique these drawbacks will disappear. In contrast with the foregoing putative good results it may be interesting to know that Hogner (*Boston Med. and Surg. Journal*, June 27, 1895) used intravenous injections of sublimate in a severe case of syphilis and experienced neither bad effects nor any therapeutical result whatever.

It may be well to remember that Ullmann very promptly caused death in the lower animals when, in a series of experiments, he injected the bichloride into their veins.

Acting on the assumption that syphilis is a bacterial disease, and that its virus animatum and its poisons may be neutralized or destroyed by the serum of animals which are known to be immune to the infection, or by the serum of syphilized individuals, an antitoxin-serum treatment has sprung into vogue. The basis of this treatment is well expressed in Klein's statement which reads: "When an animal has passed through one attack of a given infectious disease—that is, when an animal has served as a host for the growth and multiplication of a particular pathogenic bacterium—it is found that its blood has acquired a peculiar faculty. The blood has become capable not only of inhibiting the further growth of the bacterium, but also of neutralizing the toxins produced by the bacterium. Animals, therefore, which have acquired immunity possess in their blood a something that they had not before, and this substance belongs to a group of substances called antitoxins." The net results of the injection of the serum of animals as practiced by Tommasoli, Sartori, and Kollman have no scientific value whatever, and the procedure seems to have been abandoned. On the other hand, the method practiced by Bonaduce, Pellizzari, Fournier, and Feulard, who used the serum of a patient suffering from hereditary and acquired syphilis, is being much tried.

Cotterell (*British Jour. of Dermatology*, November, 1895) has treated eighteen cases by the use of hypodermic injections of serum of syphilitic individuals. He found that the serum of persons affected with secondary syphilis was more active than that of those in the tertiary stage. The gross results obtained were rapidity and efficiency of action and the improvement of the patient's health. This author, however, admits that the number of cases was too small and the time of observation too short to warrant him in drawing definite conclusions.

Vievorovsky (*Medical Week*, October 4, 1895) treated five patients suffering from secondary syphilis, by hypodermic injections of the blood-serum of robust subjects having tertiary gummata. The number of injections in each case was from 21 to 23. It is said that chancres were promptly healed; that early rashes and mucous lesions disappeared, but that relapses occurred in spite of the treatment. It is further to be noted that the relapses were much more refractory to the injections than the early rashes were, and that mucous patches were particularly rebellious to this method.

One is scarcely prepared to think that this syphilitic serum-injection treatment would be used as a prophylactic against syphilis, yet Rochon comes cheerily forward and gives his experience in this direction. This author (*Médicine moderne*, May 22, 1895) reports the case of a man who had coitus with a woman who had active syphilitic lesions on the labia majora and minora. Three days after this assumed infecting intercourse hypodermic injections of serum from the blood of syphilitics was begun. In the first three injections the serum was derived from a person who had contracted the disease nine years previously; then followed three injections derived from the blood of a person syphilitic five years, and two from a person in the eighteenth month of the infection. Rochon rather hesitatingly ventures the opinion that perhaps this vaccination did have a prophylactic effect. The man experimented upon is said to have escaped unscathed.

It is well to remember that no scientific value can be placed upon the facts presented by a few haphazard cases observed for only a short time. The tendency of very many who try new remedies and new methods of treatment in syphilis and in other morbid conditions is to rush heedlessly into print with reports of cases which should be observed for years, instead of months. In syphilis the mere dissipation of certain rashes or the disappearance of certain symptoms in reality amounts to very little in estimating therapeutic effects. To judge correctly of the efficacy of a drug or a mode of treatment we need records of at least fifty treated cases carefully watched during no less a period of time than three or four years.

ROBERT W. TAYLOR, M.D.

ECHOES AND NEWS.

IT is very fitting that Sir Joseph Lister should act as chairman of the British section of the international memorial to Pasteur.

DR. GEORGE H. ROHÉ, secretary and treasurer of the Rush Monument Committee, reported on March 31, 1896, $3729.39 as his total receipts to that date.

DURING the excitement of a recent fire that destroyed a large hospital at Lille, several patients died of shock before they could be removed. But the fatality did not cease at this, for ten sappers, who were removing medicines from the drug department, indulged in drinking what they took to be liquor, in consequence of which four died in spite of prompt attention.

GOVERNOR MORTON has signed the bill making appropriation of seventy-five thousand dollars for the Craig Colony of Epileptics.

THE New York Health Board has instructed Dr. Charles S. Benedict, Chief of the Bureau of Contagious Diseases, to find out where the milk comes from which every child who is taken with a contagious disease has been drinking.

FOOTBALL accidents in England are strongly in evidence during the last two weeks of March. Three players suffered fractures of the larger bones, while a fourth received a probably fatal injury to his neck, followed immediately by paralysis.

IN the current number of the *British Medical Journal* a case of severe opium poisoning, treated with strychnia and permanganate of potassium, is reported by B. W. Gowring, M.R.C.S. His success seems to have been properly accorded to the potash.

THE bill to repeal all quarantine acts in the United Kingdom was introduced by Mr. Russell, member of Parliament, on March 23, 1896.

IN Cleveland, Tenn., two leading physicians died of blood poisoning within a week. It is not stated just how they became infected, but it is presumed that it occurred during their professional work.

BELLEVUE HOSPITAL MEDICAL COLLEGE graduated a class of ninety-seven last month. The successful candidates for appointment in the Bellevue Hospital were: 1. Raleigh William Baird, Texas; 2. Allie Walter Williams, Georgia; 3. William A. Chisholm, Nova Scotia; 4. Charles Blount Slade, Georgia.

MUCH relief will be afforded the most densely crowded tenement district of New York City by the establishment of the proposed parks. Some conception of the overcrowding in these regions can be formed when it is stated that one block contains 1650 inhabitants.

THE bill before the Legislature at Albany to establish for pay-patients a diphtheria and scarlet fever hospital, near East River in New York City, passed the Senate on April 2d.

DR. PENDERGAST, health officer of Cincinnati, states that his investigation has shown that the pipe used for beer pumping in saloons generates a dangerous poison.

CONTRARY to what was announced in the early experience with the X-ray, two Paris experimentors have succeeded in obtaining the skiagraph of a letter through the envelope enclosing it.

AN English photographer who sent out a picture of a foot showing an imbedded needle, received a telegram

from a customer saying: "Photograms received, very tame. Send more sensational ones, such as interior of belly, backbone, brains, liver, kidneys, heart, lungs, etc."

A NEW ambulance for Bellevue Hospital was put into use yesterday. It is known as No. 6, and is said to be the finest ambulance ever constructed in this country. It stands about a foot higher than any of the other ambulances, and weighs only 1300 pounds. The wheels of the vehicle are equipped with solid rubber tires two inches thick.

A BROKEN needle embedded in the fleshy part of a woman's hand was drawn out by a powerful electro-magnet, improvised at the electric light works in Cherryfield, Me., the other day.

A CREMATORY is being erected at Liverpool, making the third in England. The others are at Manchester and at Woking; there is also one at Glasgow. Woking had 150 cremations in 1895, making its total number 733.

UNDER a recent order of the Postmaster-General, relating to periodicals, back numbers and reprints of newspapers, magazines, and all other periodicals, cannot be mailed as periodicals, but must pay postage as books. The publishers say that this order will cause much inconvenience.

IN the French departments, where forests have been cut down, there has been a marked decrease in the number of births, and an increase in that of deaths during thirty years. In the last five years the excess of deaths over births was 89,682, and the mortality in the departments was nine times as great as in the rest of France.

THE medical officers of New York State militia are dissatisfied with the present insignia, which is a shield of embroidered gold. This, it is claimed, is a designation entirely out of place for the Medical Department and practically represents nothing. The insignia that is desired is the Geneva cross, which is known throughout the world, and at once makes known the presence of the medical officer. Surgeon-general Terry has the matter under advisement.

REMARKABLE courage was displayed by Mary Farrel, the laundress whose arm was amputated at Bellevue Hospital Sunday. The young woman while at work in a hotel laundry had her left hand caught in a large steam wringer. The hand and wrist were terribly crushed. The doctors decided on an immediate amputation below the elbow joint. The patient positively declined any anesthetic, and the operation was done without it, the patient proving an interested spectator of the procedure.

A MAN giving his name as Santanelli arrived in Fort Wayne, Ind., recently and gave some private exhibitions of hypnotism. On Monday night, March 30th, he placed James Mahoney, a youth, under hypnotic influence. Since that time Mahoney has been in a comatose state, closely watched day and night by a committee of medical students. This action of Santanelli has caused indignation among the physicians who assert Mahoney will suffer serious injury as a result. Santanelli has been arrested on the charge of cruelty to a minor. This is the first case of this kind ever tried in court.

A SOCIETY has been organized in New York, under the name of the Improved Housing Council, for the purpose of providing suitable dwellings for the tenement-house population. Specifications have been given and the architects of the city invited to submit plans for a suitable type of building adapted to the conditions which prevail in New York. The plan embraces a group of houses, six stories high, designed for an entire city block, and realizes the most recent and approved ideas for light, air, privacy, safety, and comfort.

HENRY J. JORDAN, thirty-nine years old, of 78 West Eighty-fifth street, has been indicted by the grand jury for practising medicine without a license at 21 West Nineteenth street. It is alleged that he has been practising under a diploma of the Philadelphia Medical College that was held by Henry J. Jordan, now dead. The diploma was granted in 1867, which date, it is alleged, has been altered to 1879. The County Medical Society has charge of the prosecution.

THE following is quoted from the recent Goulstonian lectures on "The Life History of the Malaria Germ Outside the Human Body," by Dr. Manson of England: "If it is established, as I believe that ere long it will be, that the plasmodium is a parasite of the mosquito, that malaria is a disease of insects, we may look for some strange scientific and practical developments. The discovery will spread before us a vast field for future study. The real science of malaria will only be begun."

A CASE of death from the use of antitoxin is reported from Wheelersburg, O. On the 22d of March a practitioner, who has had considerable experience in the use of serum, injected the usual prophylactic dose over the scapula of a sleeping child of five years. An hour before he was known to be in perfect health. In less than five minutes the doctor was summoned from an adjoining room to find the child dead.

THE town council of Alameda, Cal., has taken the initiative in advanced ideas of caring for tuberculous patients. An ordinance requires that all persons ill with consumption shall be reported by their physicians to the Board of Health, when directions will be given for their isolation and proper care. Another evidence of the growing appreciation of the contagiousness of phthisis is shown by the steps recently taken in Chicago for the erection of separate buildings in connection with the county hospitals of Chicago for the use of consumptives. Such a hospital has just been opened in Ireland.

WHAT appears to have been the final hearing of Judiciary Committee of the Massachusetts Legislature upon the antivivisection bill was had last week. Witnesses and certificates from nearly all those teaching physiology in the State were arrayed in opposition to the measure.

President Eliot, of Harvard College, strongly protested, declaring that there was no abuse of vivisection in Massachusetts.

A number of the prominent physicians of Chicago have recently allowed themselves to be interviewed by a representative of the daily press concerning their views upon cremation as compared with ordinary burial of the dead. For sanitary reasons they were unanimously in favor of fire, and expressions of strong opposition on any grounds were wanting. The writer develops the fact that a greater number of acres within the limits of Chicago were devoted to cemeteries than to parks.

The hypodermatic use of perfume is said to be a popular fad among the Parisian votaries of fashion. The injection of a small amount of violet extract imparts quite a lasting and delicate fragrance to the skin, obviating the inelegance of such applications to the linen.

Considerable interest is being manifested in measures now pending in Congress relative to the hospital corps of the army and the marine hospital service of the navy. The objects aimed at by the bills are to change the official title of apothecary in the navy to pharmacist, to raise his rank to that of a warrant officer and to increase his pay. In the army the bills provide for a change of title from hospital steward to pharmacist, to promote the rank from that of first sergeant to sergeant-major and to increase the pay from $45 to $75 a month.

The following is a list of the medical societies and associations that hold meetings between the 10th and 30th of the present month: Medical Association State of Alabama, at Montgomery, April 21–24th; Arkansas Medical Society, Fort Smith, April 29th; Medical Society State of California, Los Angeles, April 21st; Medical Association of Georgia, Augusta, April 15th; Iowa State Medical Society, Des Moines, April 15th; Medical and Chirurgical Faculty of Maryland, Baltimore, April 28th; Mississippi State Medical Association, Vicksburg, April 15th; South Carolina Medical Association, Spartanburgh, April 22d; Tennessee State Medical Society, Chattanooga, April 14th; Texas State Medical Association, Fort Worth, April 28th.

A well-dressed young man, who represented himself as a health inspector, called at a bakery at 783 Third avenue, Brooklyn, on Monday evening and induced the young woman, who was in charge, to accompany him to the sidewalk on the pretense of looking at some defect in the gutter. Simultaneously, another young man, the confederate of the "inspector," entered the store and rifled the money-drawer, containing $10.

Anti-vaccinationists in this country may well ponder on the experience through which the citizens of Gloucester, England, are now going. For years that city has been a centre of the anti-vaccination craze, and so prevalent there was this particular form of idiocy, that the law in regard to the employment of this safest and most certain of all the prophylactics known to medical science, has long been a dead letter. A whole generation of helpless children was allowed to grow up unguarded, and every school became simply an invitation to pestilence. Now the invitation has been accepted, and such an epidemic of smallpox is raging at Gloucester as has been rarely equaled in modern times, except among the savage tribes of Africa or Greenland. The hospitals are crowded to overflowing, business is at a complete standstill, churches and schools are closed, and toward the cemeteries moves an almost continuous procession of wagons laden with the dead.

Dr. Roger S. Tracey, register of vital statistics, reports that for the week ended at noon, April 4th, there were 922 deaths in New York City, of which 352 were in cases of children under five years of age.

Some very observant person has discovered a new affection of the eyes, caused, it is said, by the prevailing method of seating passengers in street cars. The effort to fix the gaze upon passing objects results in a strain and twitching in the external muscles of the globes, which is quite annoying.

CORRESPONDENCE.

ACUTE POISONING FROM COTTON-ROOT BARK.

Editor of The Medical News:

Dear Sir: The following case may be worth reporting as I am unable to find anything similar to it: Was called very hastily about 11.20 P.M. one Saturday in June, 1895, by Mr. R., a merchant, who stated that he had found his wife unconscious when he arrived at home from the store a few minutes before.

I soon reached the patient and found her in a state of complete muscular relaxation. The pupils were alike both widely dilated; respiration 10, sighing and shallow; pulse 150, very weak and compressible; temperature 95° in axilla.

There was a faint, peculiar odor to the breath, but no blisters on the lips or tongue, though the latter was very dark colored. I asked the husband if she was pregnant. He replied that she thought she was, but he did not. He assured me, however, "that she had not taken anything for that, because he knew she wouldn't do such a thing."

Gave apomorphia, ¼ gr., hypodermically, and diluted alcohol by the same method. Thorough emesis occurred in five minutes, the vomited matter being reddish-brown in color. The symptoms showed rapid improvement, and in half an hour she could swallow, when the stomach was thoroughly washed out, getting rid of some more reddish-brown material, which appeared like extract of cotton-root bark. In about two hours she was able to talk and stated that she took four ounces of fl. ext. cotton-root bark during the interval from 9 to 10 P.M.

She improved rapidly and the next morning was able to sit up. No further trouble occurred except that she was quite weak for a few days.

The amusing thing about it all is that she was not pregnant.

Geo. A. Blakeley, M.D.
Albany, Wis.

SOCIETY PROCEEDINGS.

THE LOUISVILLE CLINICAL SOCIETY.

Meeting, February 26, 1895.

Dr. Louis Frank presented pathological specimens with the following description: The first specimens which I present for your inspection are two ovaries, which are the seat of primary carcinoma, as shown by microscopical examination. The history of the case briefly is as follows: The patient was a woman, forty-nine years of age, who was first seen about Christmas last for some pain in the abdomen which was diagnosed floating kidney. She was under treatment for a while, later passing out of the hands of that physician. A few days before I saw her she was seen by Dr. Carl Weidner, who diagnosed some uterine or ovarian trouble.

I made a diagnosis of papilloma of one ovary. The entire pelvis was filled with a mass, the uterus being pushed anteriorly and downward against the pubic bone. It was very small in size. There was ascites, and the woman was markedly anemic, having lost in the previous six months forty pounds in weight. The case was deemed of a malignant character, and she was advised to have an operation performed, to which she consented, being operated upon one week afterward at the St. Joseph Infirmary, when these two specimens were removed. When first removed they were about twice the size they now present, there being a number of cysts throughout each specimen. The cyst enveloping one ovary has not been opened, but it contains a gelatinous or colloid material. Connected with this ovary there was a very large cyst, which extended high up in the abdomen, almost to the umbilicus. The soft wall of the larger cyst was ruptured in attempting to remove it. There were no adhesions whatsoever. At the time of the operation it was discovered that metastases had occurred, although none of the cysts had then ruptured. Several of the mesenteric glands were involved, and there were one or two spots on the intestines themselves. Before the operation we had thought there were no metastases, and for that reason had advised the operation; in fact, we did not think that it was a case of carcinoma previous to the operation, as the microscope has since shown. Of course, where metastases have taken place, results of operation are not at all favorable, recurrence taking place usually very rapidly.

This patient did exceedingly well for five days, when she became very apathetic, and finally lapsed into a sleep from which it was very difficult to rouse her. The urine had been examined twice by Dr. Weidner, previous to the operation, who found neither albumen, casts, sugar, nor any abnormal condition. At the time the alarming symptoms developed, five days after the operation, the nurse was requested to secure a specimen of the urine for examination, but by repeated catheterization none was found. The patient died forty-eight hours after the first symptoms set in without having secreted any urine; having all the indications of severe uremia. Chloroform was used as the anesthetic. There never was a symptom of sepsis, and what occasioned the uremia, unless there was some pre-existing disease of the kidneys, which was not discovered, I am at a loss to say.

The other specimen is from a case of experimental surgery, which we have been doing at the college, being a case of resection of the intestine in a dog. Silk was used, the sutures being put in from the outside in a double row. The dog recovered very nicely and lived eight weeks after the operation, when he died of obstruction. At the autopsy adhesions of the omentum were found throughout at the point of resection, and that part of the gut which was turned in still remains, having formed a valve through which it was almost impossible, with a great deal of pressure—I should say ten pounds—to force any water whatsoever, except a drop at a time. The piece of gut, after being taken out, was stretched over a faucet at the hydrant, and not a drop of water could be forced through the obstruction by the pressure behind it. Allowing the water to remain in for some time, and by stripping downward with the finger, a few drops would gradually trickle through, so there is no doubt about the obstruction being practically complete. What symptoms were produced before the death of the dog I am unable to say. The sutures are still *in situ*, and that part of the gut turned in has not disappeared.

DISCUSSION.

Dr. August Schachner: In this connection I would like to say something which has come to my notice to-day in regard to Maunsell's method of performing an intestinal resection, and which possibly might be the source of serious trouble. As we all know, in Maunsell's method of resection, the sutures take a particularly large purchase on the two divided ends of the intestine, a purchase of about one-quarter of an inch, going through all the coats of the intestine. I had occasion recently to kill a dog upon which I had performed the Maunsell's operation and found that all of these sutures were present in the form of little loops. The sutures had such a strong grasp upon the intestinal walls, that they had never sloughed away, presenting simply a row of loops, I suppose fully large enough to admit the end of a lead pencil. Now it is possible that such a row of loops, hanging into the intestine, might cause the arrest of some of the intestinal contents, and might be the starting-point for an intestinal obstruction. I do not know whether this has ever been mentioned, but I was impressed with the fact that obstruction might be brought about by such a condition after this method of resection. The dog was killed $2\frac{1}{2}$ weeks after the operation. Perfect recovery had taken place, and in the meantime another resection by a different method had been performed on the same animal.

Dr. Carl Weidner: Referring to the first case reported by Dr. Frank, there was no reason for the woman's sudden death, rather I might say for her premature death, except uremia; and the next question is, why should uremia occur? I had examined the urine of this patient before the operation, finding neither albumen, casts, nor any indication of organic kidney lesion. She did well after the operation, there being no indication of sepsis, but she died on the seventh day, symptoms of suppression of the urine having set in, and no urine was secreted for

thirty-six hours before death. There must be some severe shock which takes place in a debilitated patient, making a deep impression upon the nervous mechanism, which results in the arrest of urine. Possibly this may occur in the same manner, as we have sudden arrest of the secretion of a gland, from some shock to the nervous system. We might compare it to the effect of fright upon the digestive functions.

DR. W. C. DUGAN: I remember having seen a case in the City Hospital very much like the one reported by Dr. Frank. The patient came under the observation of Dr. Boggess in the medical ward, and he called me in to see her. The case had been under the care of his predecessor. She had been tapped two or three times for what was supposed to be simple ascites. Dr. Boggess examined the patient and found she had a nodular growth in the *cul-de-sac*, and it was on this account that I was consulted. We found a considerable accumulation of fluid in the cavity, also detected what we took to be several tumors in the pouch of Douglas, extending above the symphysis. It was decided to do an exploratory operation, but we were undecided as to just the nature of the trouble. There were indications of malignancy, rapid loss of flesh, and a general toxic condition. An incision was made and a large quantity of fluid was at once evacuated. We found the left ovary in a condition similar to the specimen exhibited by Dr. Frank, except that the tumor was very much larger. The tapping of the ovarian cyst and the leakage subsequently had allowed the papillomatous growths to become disseminated all over the intestines; I do not think that I ever saw another such condition. You could hardly put your finger down upon the intestine, but you would find several growths varying in size from a millet seed to a robin's egg. At the point where the trocar had been passed through, the omentum had become attached to the abdominal wall, and for a space of several inches there were large deposits all over the viscera. This patient went on very much as the case reported by Dr. Frank, and died without any septic condition, and the only explanation we could suggest was that she simply died from the intense poison from the carcinomatous tissue.

DR. W. H. WATHEN: I was present at the operation reported by Dr. Frank, and when the woman was returned to her room I expressed the belief that she would make an uninterrupted recovery. I am not surprised that Dr. Frank should have stated that there was no sepsis, because I hardly see how there could have been any. The symptoms must have been due to the character of growth that was removed. Cases of carcinoma of the ovaries do not endure operative interference well, and I presume the patient never entirely rallied from the shock of the operation; the kidneys finally ceasing to secrete urine, she died.

DR. LOUIS FRANK: I agree with Dr. Dugan that rupture of these papillomatous and cancerous tumors do cause metastases; papillomatous tumors that rupture very often take on, even after rupture, carcinomatous degeneration, as they do also sometimes before rupture. It is very difficult, and sometimes quite impossible, to tell, macroscopically or microscopically, papillomatous from true carcinomatous tissue, and it is absolutely impossible to determine by either way the point where they merge into one another, or, at times, even clinically. Papillomatous tumors are at times cancerous in character, and, so far as the life of the patient is concerned, they may be regarded almost always as malignant.

As to the justifiability of the operation, I believe that unless there are metastases, or that the patient is in such a weakened state from cachexia or cancerous poisoning, these operations are justifiable; and in looking up the subject I find that Sir Spencer Wells, Lawson Tait, and, others say that they are justifiable. Those who say they are not justifiable seem to be in the minority, though among them are such names as Schröder, who is now dead, and other equally eminent authorities. The French authority, Pozzi, also thinks that the operation is perfectly justifiable, and all authorities, with few exceptions, agree that exploratory incision should be done in all cases, as relief of the ascites alone gives the patient material comfort and lessens the pain present.

DR. W. H. WATHEN: I believe the question of secondary infection of the peritoneum was suggested by the remarks of Dr. Dugan. We found in Lawson Tait's work this subject discussed thoroughly, and he mentions a case where he opened the abdomen and removed a very simple insignificant-looking intra-ligamentous cyst, the patient made a speedy recovery, but died within three months from diffuse malignant disease of the abdominal viscera. We never know from the physical appearance of one of these tumors, or from the physical characteristics of the liquid contained within a cyst of this character, whether the disease is then malignant, or whether it will finally develop a malignant form of trouble. You cannot diagnose a case such as Dr. Frank has reported, or say whether it is malignant or benign until you have opened the abdomen and come in contact with the diseased structures; and you cannot then always make a diagnosis, in fact, very often you cannot. There are some of these papillomatous tumors where the papillomata may be within the cavity of the cyst; where they may have filled the cavity of the cyst penetrating its walls; or where papillomata may have developed upon an ovary that looks macroscopically to be positively malignant, but we find that many of them are not malignant because the patients recover from the operation and remain permanently well.

A little over three years ago a lady from the interior of this State consulted me, having at least four gallons of ascitic fluid in her abdomen, and with a tumor larger than one's fist upon each side. She was very much emaciated, and did not weigh over eighty pounds when the liquid was removed. She was so very feeble that it did not seem possible she would withstand an operation. She recovered from the operation and returned home within a little over two weeks, became fleshy, and has had no trouble since. I removed two of the most typical papillomatous ovaries that I have ever seen, and expected that there would be a return of the trouble within a very short time. We sometimes operate and remove papillomata or cysts arising in the ovary, and find during the operation that the peri-

toneum covering the bowels, and probably the mesentery, the omentum, and the abdominal walls, are studded with papillomata, and we expect the patient to die, but she recovers and the papillomata all disappear.

Therefore, I say that these operations are justifiable, if the patient is in such condition as to withstand surgical treatment, because we cannot tell whether the disease is malignant or not. If it is malignant and we can remove all the diseased structures, I then claim that operation is still justifiable.

REVIEWS.

A Manual of Physiology, with Practical Exercises. By G. N. Stewart, M.A., D.S.C., M.D., D.P.H., Professor of Physiology Western Reserve University. Published by Baillière, Tindall, & Cox, London. Sold by the Cleveland Medical Publishing Co., Cleveland, O.

By a combination of systematic exposition and specific directions for coincident practical work, this manual is designed to meet the needs of modern methods in teaching physiology. Actual contact with the facts not only develops ability to manipulate and observe, but is essential to the acquisition of an adequate knowledge of the science. The author recognizes this, and the great advantage to the student of corresponding didactic instruction and practical work throughout the course. The book is arranged to accomplish this by a section of "Practical Exercises" after the systematic description of each of the various subdivisions. The exposition of the subject is specially clear and concise, and takes cognizance of the results of the most recent researches in the domain of physiology. The value of the comparative method in investigation and study is well emphasized. As the manual is adapted to the use of students in medicine, this feature of the work is of much importance in view of the fact that many of these students lack the preliminary training in biological science which serves to acquaint one with the far-reaching relationships of morphology and physiology, and with the fact that the structures and functions of the human body are but parts of a great plan. The book is well illustrated, many of the cuts being new. The "Practical Exercises" are frequently accompanied by sketches of the animal with the apparatus arranged for experimentation, and these drawings will prove helpful. Such a manual as Dr. Stewart's admits of variation in the arrangement of topics and of elaboration in laboratory procedures if desired, and it will prove a valuable help to teachers and students, both as a text-book and as a guide in laboratory study.

System of Surgery. Edited by Frederic S. Dennis, M.D., Professor, Principles and Practice of Surgery, Bellevue Hospital Medical College; Assisted by John S. Billings, M.D., LL.D. Edin. and Harv., D.C.L. Oxon., Deputy Surgeon-General U. S. A. Vol. III. Philadelphia: Lea Brothers & Co., 1895. Pp. 919.

This volume maintains the reputation established by the preceding volumes, both as to the ability of the authors, and the practical character of its papers. The subjects embraced in this volume relate to the surgery of the regions of the mouth, larynx, and trachea, neck, chest, eye and ear, skin, genito-urinary system, and to syphilis. The number of authors is twelve, and among them we recognize many of the leading writers of this country. All of the authors are American surgeons.

The surgery of the larynx and trachea is treated by Professor Delavan, of New York. Some features of the diseases discussed, of much practical interest, are too cursorily considered. The proper operative procedure in peritonsillar abscess may involve external incision, and the exact limits should be defined. The approach to the abscess by a blunt instrument, as a director, is of the first importance. A quite similar operation is required in some cases of deep and diffuse retro-pharyngeal abscess, but the author only alludes to it, without noticing the precautions necessary to success. There is also no allusion to those troublesome cases of "recurrent tonsilitis," now so successfully treated by the method of Leland of Boston, with a hooked knife with which he tears away the partitions between the crypts. Professor Mudd of St. Louis, treats of the diseases of the mouth and tongue; Professor Porter of Harvard University, of the diseases of the salivary glands; and Dr. Willard Parker of New York, of the surgery of the neck. Professor Dennis discusses the surgical injuries and diseases of the chest, and introduces, at the close of his paper, Bryant's method of relieving esophageal and bronchial obstruction by way of the posterior mediastinum, with illustrations. The diseases of the eye are treated by Professor De Schweinitz of Philadelphia, and the operative surgery of the eye by Professor Noyes of New York. Dr. Gorham Bacon of New York, furnishes an article on the surgery of the ear, in which he discusses mastoid disease in a very practical manner. The surgical diseases of the jaws and teeth are treated by Professor Tiffany of Baltimore, and the surgical diseases of the skin by Professor Hardaway of St. Louis. The surgery of the genito-urinary system is exhaustively treated by Professor White of Philadelphia, assisted by Dr. Wm. H. Furniss. This article occupies 331 pages, and is in itself a very complete treatise on that subject. Professor White discusses the question of castration for hypertrophy of the prostate approvingly. The last one hundred pages are devoted to the subject of syphilis, by Professor Taylor of New York. His name is a guarantee of the high character of the article.

A Pictorial Atlas of Skin Diseases and Syphilitic Affections, from models in the Museum of the Saint Louis Hospital, Paris, with explanatory woodcuts and text, by Ernest Besnier, A. Fournier, Tenneson, Hallopeau, Du Castel, Henri Feulard, and Léon Jacquet. Edited and annoted by J. J. Pringle. Published by F. J. Rebman, London; W. B. Saunders, Philadelphia. In twelve parts.

An examination of Parts I and II of this recent addition to pictorial dermatology, excites a feeling of mingled admiration and astonishment. One cannot help admiring the artistic excellence of these plates and noting their life-

like appearance, which seems more striking, when it is remembered that they are not taken from life, but from wax models of dermatological cases, mostly executed by M. Baretta, for the Museum of the Saint Louis Hospital in Paris. This famous collection is well known to most dermatologists in America, and it is a source of congratulation that many of the typical representations of common skin diseases, which heretofore could only be studied upon the shelves of the museum, are now brought to the notice of the profession in this country by means of this new and excellent atlas.

In Part I are four photo-lithochromes, representing lupus vulgaris, dermatitis herpetiformis, syphilitic chancre of the vulva, and purpura hemorrhagica.

In Part II, we find representations of lupus erythematosus, hypertrophic rosacea, circinate papulo-squamous syphilide, and Xanthoma planum et tuberosum.

When all of the plates are so worthy of commendation, it seems unjust to discriminate, but the illustrations of erythematous lupus and the circinate syphilide are remarkably fine, and perhaps deserve special mention. The text accompanying the plates furnished by the various authors, is concise and practical, and gives, in addition to a brief history of the case, a commentary on both the case in particular and the disease in general, which will prove of interest and value to the reader. A number of woodcuts are scattered through the text and serve to emphasize or elucidate points of differential diagnosis and other matters to which reference is made.

Therapeutics of Infancy and Childhood. By A. Jacobi, M.D., Clinical Professor of the Diseases of Children in the College of Physicians and Surgeons (Columbia University), New York, etc. Philadelphia: J. B. Lippincott Company. 1896. Pp. 518.

To the readers of the *Archives of Pediatrics* of the past dozen years, much of the material in this book will have a familiar, but not unwelcome appearance, for it has been compiled by the distinguished author from contributions to many numbers of that journal, additions and corrections being made, of course, where indicated.

A work like this, the product of a mature mind, rich in the experience of the subject at issue, is a distinct gain to medical literature. It has long been a matter of surprise that one so well qualified to instruct the general profession, has delayed so long to present his views in comprehensive form. Perhaps it can best be explained by the great activity of the author's life, and the consequent inability to devote the time necessary for such a service. Of course, the profession is the gainer by the delay in the maturity and breadth of treatment of the subject.

Dr. Jacobi is a believer in drugs, we are therefore prepared to learn that his understanding of therapeutics is no mere generalization of statements, no exposition of his broad knowledge of hygiene and dietetics alone, but a comprehensive application to the treatment of disease in children of methods of diet and hygiene when these are indicated, or, of the use of the great variety of materials which are to be found in the pharmacopœia, if such would seem to him more appropriate. One will look in vain in his pages for the highly advertised proprietary remedies. Such a plan may be carried too far, for while overadvertised or loudly advertised remedies certainly tend to make one suspicious as to their real merit, it does not follow that they are necessarily without value, and one should be allowed to chose from among them those which have merit, which can be positively determined, even though the methods by which they are distributed may be objectionable.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 25, 1896, TO MARCH 30, 1896.

Leave of absence for two months and fifteen days, with permission to go beyond sea, is granted Captain Charles F. Mason, assistant surgeon U. S. Military Academy, West Point, N. Y.

The leave of absence for seven days granted Major Joseph K. Corson, surgeon U. S. Army, Fort D. A. Russell, Wyoming, is extended twenty-three days.

First Lieutenant William F. Lippitt, Jr., assistant surgeon, will report in person to Major Henry S. Turrill, surgeon, president of the examining board appointed to meet at Fort Riley, Kan., on Tuesday, April 14, 1896, at 10 o'clock A.M., at such time as he may be required by the board for examination as to his fitness for promotion.

Leave of absence for two months, with permission to apply for an extention of two months, is granted Major Curtis E. Price, surgeon, Fort Sill, Ind. Ter.

First Lieutenant Henry C. Fisher, assistant surgeon, is relieved from duty at Fort Yates, N. Dak., and ordered to Plattsburgh Barracks, N. Y., for duty.

The following-named officers will report in person to Lieutenant-Colonel Charles R. Greenleaf, deputy surgeon general, president of the examining board, appointed to meet at San Francisco, Cal., on Tuesday, April 14, 1896, at 10 o'clock, for examination as to fitness for promotion: First Lieutenant Merritte W. Ireland, assistant surgeon; First Lieutenant Benjamin Brooke, assistant surgeon; First Lieutenant George M. Wells, assistant surgeon.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING, MARCH 26, 1896.

March 10.—Medical Inspector J. B. Parker to duty in charge of Naval Hospital, Widow's Island, Me., in addition to present duties.

March 11.—Surgeon Thomas Owens placed on the retired list March 10.

March 13.—Surgeon W. R. DuBose detached from the Naval Academy and ordered to the "Terror."

March 16.—Surgeon P. M. Rixey ordered to the Naval Dispensary, Washington.

Assistant Surgeon H. La Motte detached from the Naval Hospital, Chelsea, Mass., and ordered to the receiving ship "Franklin."

Surgeon G. E. H. Harmon detached from the Naval Dispensary, Washington, and ordered to the Naval Academy.

P. A. Surgeon C. H. T. Lowndes ordered to the Washington Navy Yard.

March 23.—Passed Assistant Surgeon B. R. Ward detached from Coast Survey Steamer "Blake" and ordered to the "San Francisco," holding survey on Chaplain J. J. Kane in London, en route.

March 27.—Surgeon J. C. Wise ordered to examination for promotion March 27.

THE MEDICAL NEWS.
A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXVIII. NEW YORK, SATURDAY, APRIL 18, 1896. NO. 16.

ORIGINAL ARTICLES.

ON THE NATURE AND TREATMENT OF EXOPHTHALMIC GOITRE, WITH SPECIAL REFERENCE TO THE THYROID THEORY OF THE DISEASE AND TO THE TREATMENT BY THYROIDECTOMY.[1]

BY M. ALLEN STARR, M.D., PH.D.,
OF NEW YORK.
PROFESSOR OF DISEASES OF THE MIND AND NERVOUS SYSTEM, COLLEGE OF PHYSICIANS AND SURGEONS, MEDICAL DEPARTMENT OF COLUMBIA UNIVERSITY; CONSULTING NEUROLOGIST TO THE PRESBYTERIAN AND ORTHOPEDIC HOSPITALS, AND TO THE NEW YORK EYE AND EAR INFIRMARY.

THE THEORIES OF THE NATURE OF EXOPHTHALMIC GOITRE.

EVER since the early descriptions of exophthalmic goitre by Graves in England in 1835, and by Basedow in Germany in 1840, the nature of this affection has been a matter of debate. Numerous theories have been offered to account for the disease, but one by one they have been discarded, for each in turn has failed to account for all the symptoms presented by the patients. The theory of cardiac disease, organic or functional, was the first one to be abandoned. The theory of disease of the sympathetic nerve was largely hypothetical, being based upon an erroneous physiological conception of the action of the sympathetic nerves and upon very doubtful pathological findings. The theory of a primary disease of the vasomotor centre in the medulla oblongata appeared to have a greater amount of support than any other, yet even this had many weak points, and the fact could never be forgotton that in many cases of disease no lesions were found in this region after death. The theory that a general neuropathic constitution predisposed to the disease was doubtless true, but alone, hardly accounted for its development and has been justly looked at with suspicion in England and America, for every physician has seen the disease develop in persons of good nervous constitution. The theory of toxic influences originating in intestinal indigestion has an element of improbability, for this is a common condition while Graves' disease is a rare affection.[2]

It is only within the past few years since the more accurate knowledge of disease of the thyroid gland has been reached by physiological experimentation, by clinical observation in cases of myxedema, of cretinism, and of the various forms of goitre, and by pathological investigations, that a clue has been reached to the problem of the origin of Graves' disease.

The theory which I wish to urge that exophthalmic goitre is due to hyperactivity of the thyroid gland is by no means an original one. It was first proposed by Möbius[1] of Leipsig, in 1886, and in spite of most vigorous opposition has been gradually gaining ground during the past ten years, being now accepted by many authorities in Germany, by Brissaud,[2] Regnault,[2] Joffroy,[2] Boinet, and many others in France; by Greenfield,[3] Maude,[4] Adam,[5] Murray,[6] and Bramwell in England, and by many careful investigators in other countries. It is because the evidence in favor of this theory is not sufficiently appreciated by American physicians that I have brought it forward at this time. In but few American articles has it been discussed, viz.: by Dr. J. Arthur Booth, *Jour. Nerv. and Ment. Diseases*, August, 1894; by Dr. A. R. Oppenheimer, *Ibid.*, April, 1895; by Dr. Stieglitz, *N. Y. Med. Monatschr.*, June, 1895, and by Dr. James J. Putnam, "Trans. Mass. State Med. Soc.," 1895.

I have become converted to this theory by my own experience in the study both of exophthalmic goitre and of myxedema, and I am sure that anyone who has had occasion to observe these two diseases, to notice the striking contrast between them, or to watch the effect of the administration of thyroid extract in myxedema, in cretinism, or in the reduction of obesity, must have been impressed very strongly with the fact that the symptoms of exophthalmic goitre are due to an excess of thyroid secretion in the blood.

This theory will seem more probable if we contrast the symptoms present in myxedema with those present in exophthalmic goitre, and if we

[1] Read before the New York Neurological Society, April 7, 1896.
[2] In 13,520 cases, in the Nervous Department of the Vanderbilt Clinic, thirty-eight cases of Graves' disease only are recorded.

study the symptoms which are produced in patients suffering from myxedema by the administration in excess of thyroid extract.

The essential symptoms of exophthalmic goitre are the swelling of the thyroid gland, the protrusion of the eyeballs, retraction of the lids, and inability to converge the eyes to a near point; the rapid action of the heart and throbbing of the arteries; the burning and perspiring of the skin; the intense nervous excitement with tremor, sleeplessness, and mental irritation; occasional diarrhea, of a watery character; irregularity and rapidity of respiration, with sense of dyspnea, especially on any exertion, and sudden exhaustion, with occasional giving way of the limbs.

CONTRAST BETWEEN MYXEDEMA AND EXOPHTHALMIC GOITRE.

1. It is hardly necessary to mention the fact that in myxedema there is a *primary atrophy* of the *thyroid gland*, or else a destruction of the gland by some cystic growth which may result in the production of myxedematous symptoms associated with a goitre. There are tumors of the thyroid gland whose result is the destruction of the gland tissue by the tumor tissue, and it is in this class of goitre cases only that treatment by thyroid extract, which, as we shall see, is the worst possible form of treatment in exophthalmic goitre, has been of some service.

2. The *appearance of the eyes.* In myxedema there is a marked tendency to abnormal heaviness of the eyelids, so that the upper lid falls and the eyes are never widely open. This falling of of the lid appears to be independent of its thickening by the myxedema. There is also a retraction of the eyeball. I have noticed in all of my cases after a cure of the myxedema that the eyeball had been previously decidedly retracted, so that when the patient was cured and the eyeball was in its natural position the previous retraction, as shown by photographs, became noticeable. The narrowing of the palpebral fissure, by the semiclosure of the eyes, adds to the dull, lifeless expression of the face in myxedema and gives the patient the sleepy look.

In exophthalmic goitre the eyes are abnormally widely open. And even in the cases in which the exophthalmus is not sufficient to interfere with the movement of the upper lid there is a tendency to retraction of this lid so that it does not descend in a normal manner when the patient is told to look downward (Graefe's symptom). The lower lid is also slightly retracted in exophthalmic goitre (Stelwag's symptom). This is more noticeable when the eyes are prominent, but even when they are not it is quite common for the sclera to be visible all around the iris in this disease. The prominence of the eyeballs is of course one of the three chief symptoms, and is, at times, a very painful one, leading occasionally to ulceration of the cornea.[1]

3. The *condition of the heart and arteries* in myxedema is exactly the opposite of the condition found in exophthalmic goitre. In all the cases of myxedema a slow pulse is present. In one of my cases it was habitually 60, in another 62. The pulse is also small and of high tension in myxedema. It is well known that myxedema has been occasionally mistaken for Bright's disease, usually for the form of chronic interstitial nephritis or contracted kidney in which there are high tension pulse, edema, albumin, and hyaline casts in the urine, and nervous symptoms, such as headache, and inability to use the mind.

In sharp contrast to this condition are the rapid, full, large pulse and throbbing arteries, constantly complained of in exophthalmic goitre. As a result of these dilated blood vessels, we have the pulsation of the goitre, the bruit in the neck, and the intense flushing and heat of the skin and the marked increase in the perspiration. In none of my cases of exophthalmic goitre, has the pulse been less than 100 per minute, and often it has risen to 150.

4. *Skin.* In myxedema the skin is thickened, is rough and scaly, is dry, is apt to crack, does not perspire, and the growth of the hair is impaired. The hair becomes dry and brittle, and falls out: the nails become ridged and thickened, and both nails and skin are abnormally discolored by a deposit of blackish pigment beneath the epidermis. The electrical resistance is increased in myxedema on account of the thickness of the skin.

In exophthalmic goitre the skin is particularly soft, thin, fine, and almost transparent, there being little of the fatty tissues naturally present beneath it, so that, as a rule, the patients appear to be slightly emaciated, especially about the cheeks and neck. It is moist, and the perspiration is constantly excessive. It is smooth, and even glossy. The growth of hair is stimulated, and the hair is oily and soft. The nails grow rapidly, and have a glossy appearance almost as if manicured. The electrical resistance is diminished in exophthalmic goitre on account of the increased moisture of the skin.

5. *Temperature.* In myxedema, the patients

[1] For cases see "Trans. of the Ophthal. Soc. of the United Kingdom," Vol. XII, 1886.

suffer constantly from a sense of cold. In warm weather they feel chilly, and in cold weather they suffer extremely from the cold. The body temperature is uniformly depressed, being 97° or 97½° under the tongue in the majority of cases. Even when these patients are warmed artificially by a hot bath or by a very hot atmosphere, they never perspire.

In exophthalmic goitre, patients suffer constantly from a sensation of heat which is at times that of disagreeable burning of the entire skin, so that they are very fond of undressing themselves and exposing their bodies to cool air. They dislike extremely to be in a hot or confined room. They perspire freely, and the temperature is actually elevated at times one-half to one degree. In one of my patients suffering from this disease the temperature was never below 99½° during three months, and often reached 101°.

6. One of the points of the greatest contrast between myxedema and exophthalmic goitre is found in the *mental condition* of the patient. In myxedema there is a particularly dull condition of the mind. It seems impossible for the patients to interest themselves in their ordinary occupation, or in matters which would, under usual circumstances, excite them to mental activity. They are indifferent to their surroundings; they are content to remain without occupation, sitting listlessly, not exerting themselves in any manner, and not occupying their minds in any way. This state of indifference is often attended by a condition of depression, a depression different entirely from that of melancholia, for it is not attended by delusions or produced by a train of thought, and there is none of the variation in the degree of depression which is so commonly observed in true melancholia. In myxedema, hallucinations are quite a prominent symptom. These are chiefly hallucinations of sight, animals and faces being seen chiefly in the evening or at night, and sometimes hallucinations of sound occur, voices being heard. The patients in myxedema recognize the hallucinations as products of the mind. They do not become the basis for delusions, and although annoying they do not lead to insane acts as in hallucinatory insanity. In true melancholia it is to be remembered that hallucinations are not at all common. It is the emotional rather than the sensory sphere which is excited. The condition of mind, therefore, in myxedema is rather to be described as one of partial dementia with some depression of spirits than as a melancholic state. The patient appears to be lacking in all spontaneous mental processes, to be sluggish in thought, and to be depressed thereby; and yet when the mind is excited to perform its ordinary work, it appears to be capable, and shows none of the defects of primary or of terminal dementia. There is never incoherence of speech. There is never the lack of reasoning power.

Let us contrast this condition with that present in exophthalmic goitre. It is a characteristic symptom of patients suffering from this disease that they are mentally alert, extremely active and rapid in all mental processes, and are in a state of psychical excitement. They are quick to catch an idea, imaginative and eager, sanguine and energetic, and are conscious themselves of an unusual flow of thought and intensity of emotion. They even complain that the insomnia from which they suffer is due to the fact that they cannot stop thinking, and they are conscious of a state of mental activity which is unnatural and which is perhaps comparable to the condition present in the early stage of intoxication.[1] In fact, the appearance and manner of these patients often suggests the possibility of their having been unduly stimulated. There is no periodicity in this condition of mental activity. It is not greater at one time than at another, but it is frequently attended by a positive sense of exhaustion, the patients feeling the reaction from this mental strain, and hence becoming depressed and weary after any mental exertion. It is for this reason that patients suffering from exophthalmic goitre are always unduly fatigued by social intercourse, and suffer from a period of collapse after any mental excitement. It is well known that the rest cure, attended by isolation, by absolute mental repose, and by a cessation of all mental activity is of service chiefly in quieting the mental and nervous symptoms of this disease.

While these are the ordinary mental symptoms of exophthalmic goitre, there are cases which go on to a much more active state of mental derangement. Acute mania is known to be a complication of very serious import in the course of this disease.

It has been my fortune to have seen more than one case presenting acute maniacal conditions. One observed in 1892 was especially impressed upon my memory. In this case and in others that I have seen, the state of mental excitement did not correspond at all to that of true acute mania, and there were no hallucinations present. It was a state of abnormal mental activity which might be described as a hysterical insanity, and

[1] See also Maude, *Brit. Med. Jour.*, 1893, II., 892.

yet there were not the outbursts attended by complete loss of self-control which one is accustomed to see in cases of mental hysteria. In a word, the mental condition might be best described as the exact counterpart of the condition of dementia already described as existing in myxedema. In the one case the mind was hampered in all its action, in the other case the mind was stimulated in all its activity.

Associated with the mental activity there is commonly a tendency to physical activity in patients suffering from exophthalmic goitre. They are constantly moving about, and it is very difficult to keep them quiet, the muscular restlessness being very noticeable. There is also a constant tremor in the extremities and often in the muscles of the face. In myxedema, on the other hand, there is a sluggishness and lack of spontaneous movement.

It seems evident, therefore, by this comparison of the essential symptoms in these two diseases that they present counterparts of each other, and that in each organ or function affected in both the symptoms present in the one disease are exactly opposite to those present in the other.

I hardly need remind you that both diseases are most common in women, and both have some relation to the sexual function.

EFFECT OF THYROID EXTRACT IN MYXEDEMA.

We have thus far shown that the symptoms of myxedema and of exophthalmic goitre afford a striking contrast to one another. As myxedema is due to an absence of thyroid secretion, exophthalmic goitre may be reasonably ascribed to an excess of thyroid secretion. This hypothesis receives distinct confirmation from the facts observed in the treatment of myxedema by thyroid extract,[1] and more particularly in the effect of overdoses of this remedy. The symptoms which appear to indicate that too much thyroid extract is being given to a patient suffering from myxedema are (1) a rise of temperature above normal, (2) an increased rapidity of the pulse, (3) a burning sensation with some flushing of the skin, (4) a rapid emaciation, (5) a condition of mental excitement, and (6) exophthalmus.

THE ARGUMENT FROM PATHOLOGY.

It has been already stated that the weak point in all previous theories to account for exophthalmic goitre, has been the absence of uniform pathological findings in the cases which have been investigated. Singularly enough, pathologists have neglected to record the condition of the thyroid gland in this disease until very recently. Byron Bramwell was among the first to describe the changes in the thyroid gland. He said, in 1891, that in exophthalmic goitre the condition usually present in the thyroid was comparable to an acute catarrhal process, with great increase and an altered character of the epithelial cells, an apparent proliferation throughout the gland and a great diminution of the formed colloid material. In other words the essential change was one in which the process of secretion was greatly exaggerated and altered in character.[1] Greenfield described more fully the great significance and uniform character of the changes present in the thyroid gland, and in his interesting Bradshaw lecture,[2] will be found the most satisfactory account of what is doubtless the constant lesion present in this affection, namely: a true hypertrophy of the glandular elements of the gland with increase of its secretion, and possibly some change in the character of that secretion. His findings have been abundantly confirmed by other investigators in various countries,[3] and in all recent autopsies the same changes in the thyroid gland have been demonstrated. These changes are exactly such as would occur in a gland whose functional activity was greatly increased, and whose actual size was enlarged in accordance with this function. They are quite comparable to the changes undergone by the mammary gland during the process of lactation, not really pathological in nature, but what one might consider a physiological hypertrophy.

The objection which has been raised, that in a few cases of this disease there is no enlargement of the thyroid gland, is not a valid one. For it is perfectly possible for a gland to show a great hyperactivity without actual enlargement, as for example, the salivary glands in a state of salivation; or the mammary gland in a multipara. As to the question of the actual change in the character of the secretion of the gland in exophthalmic goitre we as yet know very little. That is a subject requiring further investigation.

CONSIDERATIONS REGARDING TREATMENT.

If the theory of exophthalmic goitre here stated is the correct one, it is necessary for us to bring into accord with it some of the successful results of the various forms of treatment which have been recommended for this disease. It is

[1] See also Canter, *Annales de la Soc. Med. Chir. de Liege*, January, 1894, p. 12.

[1] *Edin. Med. Jour.*, 1891, Pt. II, p. 1044.
[2] *Brit. Med. Jour.*, December 9, 1893.
[3] Reymond, *Bull. d. l. Soc. Anat. de Paris*, Sec. VII, No. 18; Walter Edmunds, *Brit. Med. Jour.*, May 25, 1895.

well known that a very large proportion of patients who suffer from exophthalmic goitre, recover either entirely, or for a considerable length of time.[1] Such recovery is of course inconsistant with the idea of a permanent destructive lesion of any part of the body and is only possible in a functional disturbance. If the cause of the disease is hypersecretion of the thyroid gland, a reduction of that secretion to its normal amount would result in a cure, hence there is nothing in the theory advanced that is against this successful result. But when the enormous number of remedies, which have been brought forward, are reviewed, it is not easy to understand in what way the result in any individual case has been accomplished.

If we review the various methods of treatment which have been proposed, it is perhaps possible to explain the success obtained by the theory that these various remedies have in some manner effected a diminution in the activity of the thyroid gland. Thus the remedy most employed in England is belladonna, and it is not improbable that this has a specific action upon the thyroid gland as it has upon other glands of the body in arresting its secretion. I can report a recent case, a girl aged seventeen, with all the characteristic symptoms present one year, who has been very greatly improved in two months by doses of belladonna carried to the physiological limit.

The rest cure is probably the most successful of all the methods employed in the treatment of exophthalmic goitre,[2] and this, together with the use of iron and tonics, accomplishes the purpose by quieting the general nervous irritability. And this leads us to refer to the very marked effect of the mental condition upon the symptoms of exophthalmic goitre. We know from daily experience that the mind has a distinct action upon the various glands of the body; thus the secretion of tears is almost entirely produced by mental impressions; the secretion of saliva is also markedly stimulated by sensory impressions; the secretion of gastric juice and the whole process of digestion are decidedly affected by mental conditions, as is markedly evidenced in the malnutrition and malassimilation present in cerebral neurasthenia and in the various forms of insanity. We have presumptive evidence, therefore, that the mental condition may affect the secretion of the thyroid gland, and there is an overwhelming amount of testimony to the effect that the onset of exophthalmic goitre can be traced to mental emotion, especially of the nature of fright, dread, and anxiety. It is impossible, therefore, to ignore the mutual relation between a restful state of the mind without anxiety, and a diminution or more natural secretion in the glands of the body. Hence it seems probable that the success of the rest cure in these cases is due to the little understood, but powerful effect of the mental state upon bodily functions.

Electricity is an agent which has been greatly vaunted in the treatment of exophthalmic goitre. Inasmuch as various methods of its application have met with success in certain hands and the same methods have utterly failed in others, it is difficult to determine the real value of this therapeutic agent. It is possible that it may act through the mind by suggestion. It is also possible that it may have a distinct influence upon the secretion of the gland, either by a catalytic action of the galvanic current or by a compression of the gland exerted through the muscles, which are excited by the strong faradic current.[1]

I am informed by Dr. Rockwell, whose experience is probably greater than that of anyone else in this city in the electrical treatment of this disease, that his greatest successes were obtained by means of very strong galvanic currents (60 milleamperes), applied through a clay electrode directly to the gland, and such a current would undoubtedly result in chemical changes within the gland, modifying its secretion. Dr. Putnam of Boston favors strong faradic currents causing contraction of the muscles of the neck and compression of the gland.

It is somewhat difficult to explain the favorable action secured by aconitia and veratrum viride, although the testimony in favor of these drugs is too definite to be ignored. They are both known to have a distinct action in modifying the secretion of the glands of the body. It is also possible that by their depressant influence upon the heart they have reduced materially the flow of blood through the thyroid gland, which, being near the heart, would be manifestly affected by the force of its activity. If ergot contracts the medium-sized arteries, its favorable action may be ascribed to diminution in the blood supply of the gland.

It is thus evident that the effect of remedies which have been urged in this disease can possibly be explained by their known effects in diminishing the amount of thyroid juice produced within the body.

I desire to mention one remedy which in several cases has seemed to me to be of great service,

[1] Vigoroux.

namely, the glycero-phosphate of sodium, in twenty-grain doses, three or four times a day. This was first used by Trachewsky in Kocher's clinic,[1] and was found to have the effect of diminishing the size of enlarged thyroid glands. It has also been successful in the hands of Chibret.[2] Under treatment by this drug alone, a patient in the Presbyterian Hospital was markedly benefited within three weeks. A second patient to whom various forms of treatment were given by me for one and a half years, appreciated within two weeks the fact that this remedy had been of more decided benefit in every direction than any other which had been used in the previous period.

THE TREATMENT BY THYROID AND THYMUS EXTRACTS.

It is well known that within the last few months attempts have been made to treat patients suffering from exophthalmic goitre by means of the administration of thyroid extract.[3] This has been done in a purely empirical way. The concensus of opinion, however, seems to be that the thyroid treatment for exophthalmic goitre is not only of no service, but is actually of great injury to the patients. Very numerous reports have appeared in all parts of the world to the effect that patients suffering from exophthalmic goitre have had all their symptoms markedly increased by the use of thyroid extract. Thus, in a patient of Auld[4] the symptoms of the disease which had previously subsided were all brought back by the administration of this extract. In patients of Nasse[5] and Brissac,[6] Béclère[6] and Stabel,[7] the symptoms present were very much exaggerated but subsided when the thyroid was stopped, and in one unfortunate case on record a fatal result appears to have followed soon after the use of the thyroid.

If the theory of the disease here defended is correct, if exophthalmic goitre is due to an excess of thyroid secretion, there is every reason why the administration of thyroid should be avoided.

It may be affirmed, however, that if there is a well authenticated case on record of improvement of the disease under the administration of thyroid extract, it would entirely overthrow the theory here defended. I do not think that the cases of supposed improvement, of which a few have been reported, will bear thorough and critical examination. It is well known that the symptoms of tachycardia, exophthalmus, and general nervousness, have been occasionally associated with tumors in the neck, near to, but not involving the thyroid gland. In fact, Buschan[1] has attempted to draw a sharp line between primary cases of exophthalmic goitre and secondary cases of exophthalmic goitre: the latter consisting of two or more of the symptoms of the disease co-existing with other diseases of the thyroid gland. It cannot be denied that such a distinction appears to be valid. And admitting the fact that in ordinary goitre, in which the secretion of thyroid is arrested or perverted by the existence of the tumor, beneficial results have followed the use of thyroid extract, as reported by Bruns,[2] it seems possible to explain these cases of beneficial use of the drug on the theory that the patients were really suffering from a secondary form of exophthalmic goitre.

Another fact must be mentioned in this connection, namely: that there are some statements in favor of the use of thymus extract in the treatment of exophthalmic goitre. The origin of this treatment is as follows: Owen reported a case of exophthalmic goitre cured by the use of thyroid glands given in bulk. Some months after, he published a correction of this statement, having ascertained that the patient had been fed upon thymus gland exclusively, and had never received any thyroid gland. He ascribed the improvement therefore to the thymus, and following in his steps others have tried the use of thymus in exophthalmic goitre. Watson Williams[3] reports a case very carefully observed, in a hospital, in which this treatment, like that by thyroid extract, was of positive harm to the patient.

We know at present very little regarding the thymus gland or its use. It is a structure which is known to atrophy soon after infancy, and it appears to be rudimentary in the majority of adults. There are a few observations which lend support to the statement that in exophthalmic goitre it has been found increased in size after death. Such increase in glandular structure, however, associated with exophthalmic goitre is not unknown. Thus, Bowman[4] records a case in which the lachrymal and parotid glands were much enlarged, and Higgins[5] records a case in which all the lymphatic glands within the thorax were much developed, and one writer records a case of a man whose mammary glands were as much enlarged and as tender as those of a woman in the later stages of pregnancy. This glandular enlargement subsided

soon after the extirpation of the thyroid gland, which relieved the other symptoms of exophthalmic goitre in his case.

With our present knowledge it cannot be stated whether enlargement of the thymus, if it occurs in exophthalmic goitre, is merely an homologous hypertrophy or a compensatory hypertrophy. In the former case it would be analogous to the enlargement of the thyroid gland, under which circumstances the administration of thymus would be distinctly contra-indicated. In the latter case it might be regarded as an effort of nature to combat the influence produced by the increase of thyroid secretion, and in this case the administration of thymus would be distinctly indicated. Until further facts are at hand with regard to the function of this gland, or with regard to its effects in exophthalmic goitre, we cannot reach a decision as to its use. It is always to be remembered that reports of benefit attained by the use of a remedy are more likely to be published than those of failures, and unless the testimony in favor of the use of thymus were much more voluminous and uniform than at present, I should not advise its trial.

THE QUESTION OF OPERATIVE TREATMENT.

If the conclusion thus reached is valid, that exophthalmic goitre is due to an excessive secretion of the thyroid gland, the most rational form of treatment for the disease would appear to be the removal of the gland. Yet surgical treatment is not to be undertaken rashly in this disease. We have seen already that there is a very decided tendency to recovery, either spontaneously or under the influence of treatment, and therefore it is only in the most obstinate cases of very severe type, or in the cases where life is endangered by the sudden swelling of the neck to the extent of producing asphyxia, that the question of operation is to be seriously considered. There are, however, many cases which, after a longer or shorter period, devolop such serious symptoms and remain unrelieved so long by medical treatment that the question of operation must be faced. It is therefore necessary to review such facts as can be gathered regarding the result of surgical treatment in exophthalmic goitre.

In December, 1893, Putnam collected fifty-one cases of exophthalmic goitre which has been operated upon.[1] In December, 1894, Buschan was able to collect ninety-eight cases of operation.[2] I have been able to find ninety-two additional cases in the literature of 1895, and especially in the American journals, bringing the total number of cases operated up to 190.[1] Of this number twenty-three cases died immediately after the operation. Seventy-four cases are reported as entirely cured. Forty-five cases are reported as improved, and three cases are reported as not improved; in regard to the remainder no final results are reported. The occurrence of sudden death immediately after the operation, or within two or three days of it, is a fact of very serious import. Death after these operations is not owing to hemorrhage nor to any want of aseptic precautions. In all the cases reported there have been a sudden rise of temperature to 105°, 106°, or 107°; a very rapid pulse (180 to 200); extreme nervous excitability and restlessness, with great anxiety and distress; profuse sweating, and, finally, collapse and death from heart failure. The most reasonable explanation for this series of symptoms is a sudden poisoning of the entire system by an excessive absorption of thyroid juice suddenly produced during the operation. This may perhaps be induced by the necessary handling of the gland during the operation, or by the absorption of its secretions through the open blood vessels which have been torn or divided, or from a hypersecretion of the gland with a consequent absorption going on during the operation, possibly from the effects of ether, as that is well known to be a dangerous anesthetic in exophthalmic goitre. The theory of an increased secretion of the gland is supported by the fact that in the operation advised by Jaboulay, and named by him exo-thyro-pexie (in which the tissues on the neck are divided, the gland is brought forward and left exposed to the air, but not divided or removed), there has always been noticed a large amount of thyroid se-

Many of the American cases have been put at my disposal by the surgeons themselves.

cretion exuded from the surface of the gland into the dressings. Had this extraordinary secretion been absorbed into the blood it would undoubtedly have produced poisonous effects. That manipulations of the gland of any kind are liable to produce an increase in nervous excitability and in the rapidity of the pulse is a fact which every patient suffering from exophthalmic goitre is aware. Hence they uniformly shrink from anything compressing the neck or from any attempt to handle the goitre. Such handling and pressure is usually inevitable during the operation, and seems to me to be the natural explanation for the occurrence of poisoning following the operation. It may not, however, be the only explanation, for in three cases of which I have knowledge, sudden death has followed when the goitre removed was an extremely small one. I cannot, therefore, but believe that it is possible that the secretion of the gland is stimulated by the inhalation of an anesthetic, or by the anxiety preceding the operation, and therefore believe that the operation should be done, if possible, under cocaine rather than ether, as recommended by Kocher.

It is the fact of these sudden deaths, occurring during or after operation, which has, I believe, prevented a more extensive adoption of this form of treatment in this disease, and it is because such deaths have been inexplicable that they have been so freely and fully reported. Hence I believe that the statistics already given are fairly reliable, although it may be that the percentage of deaths (12) is somewhat in excess of the truth.

It will be noticed that seventy-four cases are reported as cured. Many of these cases have been watched two, three, or four years before such reports have been made, during which time the cure has been permanent. Hence the charge cannot be made that the reports have been published too soon after the operation to determine its ultimate effects. As a rule, the cures have not resulted immediately after the operation. There has been a steady progressive improvement during two, three, or four months, until finally the cure has been reached. The first symptom to improve is the tachycardia. In one case (for the privilege of reporting which I am indebted to Dr. B. Farquhar Curtis) the pulse diminished during the operation from 120 to 80, and remained constantly below 100 after the operation. In the majority of cases the pulse has been notably slowed within twenty-four hours of the operation. The second set of symptoms to subside subsequent to operation are the nervous excitability and restlessness and the tremor. These symptoms are so distressing to the patients that the relief which they obtain in getting rid of them in almost every case leads to a feeling of great gratitude that the operation has been performed. A number of patients whom I have examined subsequent to the operation, through the kindness of Dr. Curtis and Dr. Markoe, have expressed themselves as feeling very much better, even before the exophthalmus had been at all noticeably decreased.

Together with the subsidence of the nervous symptoms, there is a gradual diminution in the sense of heat and in the perspiration and the feeling of giving way of the limbs, and the uncertainty in gait also soon disappears.

The exophthalmus persists longer than any other symptom. Some cases are reported in which the exophthalmus has persisted for a year after the operation, though in almost all cases it has been noticeably less. It finally passes away. It must be admitted that there is no reasonable explanation for the existence of exophthalmus on any of the known theories of Graves' disease. The cases which have been reported here as cured are cases in which all of the symptoms have actually subsided.

There are forty-five cases that are reported as improved. In these cases it is the exophthalmus which has remained, or the liability to a rapid action of the heart, with nervousness, on any exertion.

I think it may be said in conclusion that in the severe and intractable cases of exophthalmic goitre in which rest-cure and medicinal treatment have failed to relieve, the operation of extirpation of the thyroid gland must be considered as justifiable, and should be advocated by physicians. It should not be undertaken by surgeons hastily, or without some experience. The surgeons who have been most successful in the past few years are those who have had the largest experience in the extirpation of goitres. The respective merits of the various operations proposed cannot be discussed in this place. Some surgeons prefer an almost complete extirpation of the gland, though it is always to be remembered that a small portion of the gland must be allowed to remain, else the patient will develop symptoms of myxedema.

Some surgeons prefer the operation of tying three or four of the arteries entering the gland, although this operation is almost as difficult as that of extirpation, and is not by any means uniformly successful, the number of new vessels entering the gland being so great as to keep up its size and nutrition even after the main vessels have been tied. Others prefer the operation of

Jaboulay of exothyropexie, in which the gland is exposed, drawn forward into an open wound, and then allowed gradually to contract and dry up. This is not always successful, and leaves a very ugly scar in the neck. It is, however, safer than either of the other operations, Jaboulay having reported fourteen cases successfully treated by this method without a death.

CONCLUSIONS.

1. It seems probable that the symptoms of exophthalmic goitre are due to an excess of thyroid juice, either of normal or abnormal character, circulating in the blood and acting directly upon the vasomotor and nervous systems and upon the muscles.

2. It seems probable that the best treatment for the disease is to arrest the secretion of the thyroid gland or to remove the gland from the body.

THE MANAGEMENT OF PLACENTA PRÆVIA—WITH REPORT OF FOUR CASES.[1]

By J. NOER, M.D.,
OF STOUGHTON, WIS.

Placenta prævia is ranked by all obstetricians as one of the most formidable and dangerous pathological conditions that can be met with in obstetric practise. It is most unfortunate that there should be, among leading authorities on obstetrics, so much learned obscurity and diversity of opinion regarding the pathology and treatment of this condition. The present state of knowledge regarding the cause and the pathological changes that are responsible for this peculiar implantation if the placenta may not warrant dogmatic statements; yet it would seem that we are in possession of sufficient statistical if not scientific data to warrant very decided and positive conclusions regarding treatment. Positive conclusions may be incorrect, but they tend to produce action in a definite direction, producing results that can be estimated and weighed in the light of statistical evidence. Multiplicity of theories produce nothing but indirection, and are a source of much annoyance to the inexperienced. They are certainly often responsible for the mismanagement of placenta prævia.

"By placenta prævia," says Playfair, "we mean the insertion of the placenta at the lower segment of the uterine cavity, so that part of it is situated wholly or partially over the internal os uteri." Granted that we have a condition of this kind, what are we to do about it? A diagnosis cannot be made, nor is suspicion aroused till there is sufficient dilatation of the cervix to produce a hemorrhage more or less extensive. When this occurs the patient is probably in the seventh or eighth month of utero-gestation. Diagnosis can, as a rule, be made without difficulty at this period.

The hemorrhage before, during, and after delivery, is the all-important consideration in these cases, and to guard against this danger must be the chief aim of all treatment. By reason of the low situation of the placenta the imperfect retraction of the uterus and the tears that are likely to result during artificial delivery, the liability to sepsis is greatly increased, and must be counteracted by the most rigid asepsis.

Regarding the source and the cause of the hemorrhage authorities are at variance. It seems, however, entirely rational to *assume* that the placental site is the source of the hemorrhage, the bleeding being caused by the partial separation of the placenta due to the expansion of the lower uterine segment during the latter months of gestation. Now if the hemorrhage be due to placental separation, it must of necessity be irrational and unjustifiable to leave these cases to nature or to a mere palliative or tentative treatment. Braxton Hicks' rule,[1] viz: "After diagnosis is made, always proceed as early as possible to terminate pregnancy," is imperative in these cases. It may not, however, be possible to at once empty the uterus, hence various palliative measures, as tamponade, rest in bed, and opium may be resorted to, to gain time to obtain assistance, and to make such arrangements as may be deemed necessary for artificial delivery. The use of ergot has been quite universally condemned by recent authorities, while the use of the tampon has fared but little better. Ergot is no doubt dangerous to the life of the child, but if it be freely used it will arrest the hemorrhage, especially if the placenta be one of lateral implantation.

The following case illustrates the utility as well as the danger of ergot:

Case I.—On the night of November 8, 1890, a summons called me six miles out of town to a case of labor, a note from the attending physician stating that he had a case of placenta prævia which demanded assistance, chloroform, and forceps. The patient was forty years of age, and in labor at term with her ninth child. There had been no untoward symptoms during gestation, and labor began naturally without any suspicion of the abnormal condition till a sudden gush of blood astonished the patient and physician. Ergot was at once administered in very decided doses. This soon produced severe, almost continuous pains, which forced the

[1] Read before Wis. State Medical Society, held at Superior, Wis., June, 1895.

[1] *British Medical Journal*, November 30, 1889.

presenting head down into the pelvis, and effectually stopped the hemorrhage. When I arrived, about three hours after the first gush of blood, there was absolutely no hemorrhage, nor could any occur, as the pains were severe and continuous, the head well down in the pelvic cavity compressing the presenting placenta against its bony walls.

As the patient was suffering severely, we deemed it best to deliver at once with instruments. The patient being chloroformed, I applied the forceps and promptly delivered a large, dead child. The mother had a rapid and uneventful convalescence.

It is possible that the ergot may in this instance have been detrimental to the child's life, but as it undoubtedly saved the mother, its use must be justified.

No absolute routine rule of practise can possibly be laid down in such a way as to fit every case and condition that may arise. In a case of placenta prævia a person must apply his knowledge of the condition, and deal with the exigencies that may arise with calm judgment and logical reasoning. The situation of the placenta, whether lateral or central, period of gestation, the distance of the patient from the physician, together with the conditions as to sepsis, the operative skill of the attendant and his assistant, if he have one, will have a bearing in the management of every case. Delivery at once, diagnosis being established, by bipolar version is undoubtedly a good routine practise, and gives as good results, both as regards mother and child, as any method of treatment yet put into practise. This might not, however, be a safe or practicable procedure if you are without assistance and without operative skill, and out in the country miles distant from skilled assistance. Under these circumstances the tampon, applied with antiseptic precautions, is the most reliable temporary expedient. It should be applied in such a way, with Sims' speculum, woman in left lateral position, as to thoroughly compress the cervix and lower uterine segment. A T bandage should then be applied and the patient kept in the recumbent position. The bladder should be evacuated with a catheter under aseptic precautions.

Under these circumstances, and with the precautions enumerated, the tampon is allowable and is the most certain and safe means to control the hemorrhage. The tampon will not only stop the hemorrhage but will ordinarily bring on pains, dilating the os preparatory to delivery by operative means. The following case illustrates the utility of tamponade:

Case II.—On the night of November 27, 1892, I was called to go out ten miles from the city to attend a case of "flooding." The patient, Mrs. T. H., aged forty-one years, was pregnant 8½ months with her ninth child. The hemorrhage had ceased before my arrival, but the evidences of its occurrence were apparent in the blanched visage of the patient, the rapid, almost imperceptible pulse, and the syncope, which occurred on the slightest movement.

The bleeding must have been very profuse, as there was a stream of blood along the floor, a pool under the bed, and perfect saturation of mattress for a large area about the patient. The woman was large and stout. Physical examination revealed a softened open os, inside of which could be felt a soft, boggy mass, undoubtedly the placenta. The head of the child could be felt presenting at the superior pelvic strait. The surroundings of the patient as to cleanliness, assistance, etc., were very unfavorable. The following treatment was therefore adopted: Squibbs' ergot, 2 grms.; strychnin sulph., .005, both given hypodermically. A hot 1–2000 sublimate vaginal douche was admininistered, after which a vaginal tampon was inserted and a T bandage applied. I remained with the patient about three hours. By this time she revived and expressed herself as feeling very well. There were no further signs of hemorrhage, nor were there any labor pains. I therefore ventured to leave the patient in charge of a midwife, who was instructed how to pass catheter and not to disturb the tampon, but to let it be pushed out by the presenting head in case labor pains should come on before my return. In about ten hours I returned to find that Mrs. T. H. had a short time previously been delivered of a strong, healthy child. There had been but little hemorrhage during this time. The mother had an uneventful recovery and the child lived and prospered.

Lomer[1] of Berlin, who has carefully studied this subject and brought together a large number of cases, advocates very forcibly the treatment by premature labor and bipolar version. He says: "Induce labor at once. Turn as soon as you can get one or two fingers through the cervix. If the placenta is in your way try to rupture the membranes at its margin; but if this is not feasible, do not lose time; perforate the placenta with your fingers, get hold of a leg as soon as possible and pull it down. Do not extract the child then; let it come by itself or at least only assist its natural expulsion by gentle and rare traction." "Do away," he says, "with the tampon, as much as possible; it is a dangerous thing, for it favors infection and valuable time is lost in its application."

More than usual care should be bestowed on these cases after delivery. The loss of blood, the lacerations which are apt to occur from artificial delivery, vastly increases the shock and prostra-

[1] Professor Lomer, *Am. Jour. Obstet. and Diseases of Women and Children*. December, 1884.

tion. We have, therefore, a condition which renders our patient very liable to septic complications and *post-partum* hemorrhage. The administration of ergot, together with tonic doses of strychnia, is indicated the first week after labor. The strychnia will favor muscular tonicity, while the ergot will promote involution of the uterus and tend to prevent *post-partum* hemorrhage.

A copious vaginal and intra-uterine douche of boiled water, with some mild antiseptic like boric acid, or potassium permanganate, or creolin, should be administered immediately after labor, and an aseptic pad applied.

As an addition to the literature on the subject under consideration brief reports of the following cases are submitted:

Case III.—Mrs. C. C. E., aged forty, pregnant seven months with her eighth child, had a hemorrhage on the night of June 7, 1891. Examination to ascertain the cause of hemorrhage negative. Patient remained in bed three days, when she returned to her household duties. In about a month there was a slight recurrence of hemorrhage which ceased before my arrival. Cervix was soft and open, but placenta could not be felt by the examining finger. Treatment palliative, and patient kept quiet under close observation; two weeks later there was another and profuse hemorrhage. It occurred in the night, and had ceased before my arrival, in less than half an hour after its commencement. Placenta prævia was suspected and suggested on the second hemorrhage, but could not be demonstrated till after the third had occurred. Patient was now thoroughly tamponed under antiseptic precautions, and later delivered by version. The second day after delivery the patient had a violent chill, followed by a high temperature and the development of an extensive pneumonia. Three days after the onset of the fever there occurred a profuse uterine hemorrhage. To stop the bleeding a hypodermic injection of ergotin was given, and ice applied to the abdomen. These measures not affording immediate relief, a piece of ice the size of a small hen's egg was passed into the uterine cavity, which at once arrested the hemorrhage. A liberal use of stimulants, a few hypodermics of atropin, brought about reaction and restored the ebbing tide of life. The pneumonia was very extensive and was probably of septic origin. Gangrene of one lung occurred at a later period but the patient finally made a good recovery, after being bed-ridden for about two months.

Case IV.—Mrs. F. A., aged thirty-two, multipara. On June 29, 1893, at 2 A.M., she was taken with labor pains, an old, ignorant midwife being in attendance. The patient had bled a few times during gestation, but as it ceased spontaneously nothing was thought of it. Labor progressed naturally for about two hours when a sudden severe hemorrhage astonished the attendants. The midwife thought it might stop of itself, hence did not call a physician till bleeding had continued for three hours. Three hours more elapsed before her doctor arrived. When the doctor arrived the patient was completely exsanguinated. The doctor introduced tampon and gave stimulants pending the arrival of assistance. When I reached the scene of trouble the patient was comatose, pulseless, and delirious. The uterus still made efforts to expel its contents. The head was presenting at the brim of the pelvis, placenta being wedged in to one side. After a hurried consultation it was decided to deliver at once by podalic version as the only hope of saving the mother, the child being already dead. Version was difficult, but I succeeded in delivering the child in a comparatively short time. The mother failed to revive and expired in less than half an hour after operation.

THE IMPORTANCE OF SUPPURATIVE DISEASE OF THE MIDDLE EAR.

By CHARLES D. JONES, M.D.
of Malden, Mass.

It is undoubtedly a fact that disease of the middle ear is too lightly regarded. The number of persons who are content to attend to their affairs for months or years with suppurating ears is large, immensely larger than it would be if the disease were treated when it commenced; and much larger than it would be if it were treated at any stage of the disease. An acute suppuration is too often allowed to pursue its course undisturbed, the idea being that nothing should be done to interfere with the workings of nature.

The time to treat a suppurative disease of the tympanum is of course at its commencement, but most satisfactory results usually follow treatment even after years of suppuration; results which are occasionally as striking and satisfactory as any in surgery.

From the cases which I have had lately in private practice I have selected three for consideration. Each of these possesses details which make it peculiarly instructive:

Case I.—A girl, age eight years, was first seen February 11, 1895. One week previous she had complained of some pain in right ear. A few drops of chloroform and tr. opii. were applied locally by a member of the family and the discomfort soon passed away. But during the next few days she gradually fell into a comatose state, there were no particular symptoms, at least the family had noticed none. When first seen in consultation she was completely unconscious and presented typical cerebral symptoms of grave character. She was lying on the bed with the eyes closed; took no notice of anyone; occasionally she would open

her eyes and look at her father, but without giving any sign of recognition. Every few minutes she would shriek with a loud cry, most distressing to hear, and so loudly that conversation could hardly be heard in the room. This cephalic cry was very marked and characteristic. At this time she had not spoken for four or five days. Temperature normal, pulse good, bowels constipated, pupils equal and reacted normally to light. A little milk, which the nurse placed in her mouth, was swallowed.

Under ether the right ear was examined and the following conditions noted:

Occupying the site of the extreme posterior portion of the drum membrane was a dark-red, bulging tumor. The posterior and upper surface of the adjacent wall of the external meatus was considerably congested. No involvment of the mastoid could be made out. A thorough paracentesis was done, liberating a moderate amount of blood. No pus was seen, though a small amount could not have been detected in the presence of the hemorrhage. The ear was then cleaned antiseptically and dried out when the drum membrane was seen to occupy its normal position. It had, of course, lost its lustre and was gray and congested. The left ear was then examined. The membrana tympani looked healthy except near the posterior border, here were two or three little spots of bright red blood, which could be wiped off with the cotton probe, showing the posterior border of the membrana tympani a little congested but not bulging. A small incision made in the membrane disclosed nothing. Warm antiseptic douche in both ears. Calomel in small, repeated doses.

February 12th. After recovering from the ether she screamed but a few times and not as badly as before. Had had several hours quiet sleep. This morning she spoke for the first time in several days. Lies quietly in bed with eyes open but seems to take no notice of anything. Takes nourishment freely. Bowels had moved once. General condition much better and the ear was not inspected.

February 13th. Better: began to talk.

February 15th. Her attending physician telephoned that she was "all right and playing with her doll yesterday."

The recovery after this was without interruption.

The contemplation of this case suggests much of interest and instruction. An inflammation began in the right ear with some pain. This inflammation progressed to the neighboring regions and undoubtedly caused a localized inflammation of the dura mater near the tegmen tympani. Buck states that this is a frequent sequel in these cases. The path of connection with the dura mater may be along the sheaths of the small vessels which pierce the wall of the tympanum. In rarer cases a particularly easy entrance exists from the fact that union of the petrous and squamous bones has not taken place. This union normally occurs about a year after birth, but it may be delayed for several years, and it seems very probable that such was the condition here. Concerning the anatomical conditions I shall speak later on. The cerebral symptoms in this case point to a considerable degree of disturbance. The cephalic cry was typical. I regard the lack of speech as due to the general condition of unconsciousness rather than to aphasia from involvment of the speech centre. The symptoms were not those of aphasia, either ataxic or amnesic, and the inspection of the left ear showed that here the inflammation was just beginning and was probably of little importance in producing any of the symptoms. By paracentesis the blood vessels were depleted and free drainage established.

In treating so small a cavity as the tympanum it must not be forgotten that the space is very small. Two or three drops of pus may cause, by pressure, agonizing pain. And in the case just described the benefit of the depletion directly from the seat of disease was prompt and emphatic.

The second case furnishes a most instructive object lesson, interesting alike to the person who has a chronic suppuration of the ear and to the physician who has charge of such a case. I shall describe the facts of this case in the same order in which I learned them:

Case II.—A woman, single, age twenty-nine, had been working in a shoe factory regularly and worked during the forenoon of November 9, 1895. On the afternoon of this day she came to this city to visit friends. I first saw her at about 12.30 A.M., November 11th. (She was reported to have a chronic otitis). On the 9th she had had some nausea and vomiting and some pain in the left ear. This condition continued on the next day without particular attention being paid to it, but in the afternoon she was worse and it occurred to her friend that she was very sick, and that it was difficult to understand what she said. She was seen by a physician shortly after this and again in the evening when her condition was serious.

She was a well-nourished woman lying quietly in bed; lips very pale. When questioned she tried to answer but the speech was an unintelligible babble. The countenance was not intelligent. Temperature on preceding afternoon had been 104; now reduced to normal by phenacetin; pulse 80, and had been weak at times during past few hours.

A hasty inspection of the left ear showed some bloody pus and signs of active inflammation. Patient etherized. There was now seen near the end of the external meatus considerable macerated

epithelium which was wiped off with the cotton probe, also pus and blood. Membrana tympani intensely red but *not bulging*. A paracentesis was done in the posterior segment without altering the appearance of the membrane in any way. A small amount of blood, of course, followed the incision. A slender probe passed into the cavity of the tympanum came upon roughened bone near the fenestra ovalis. During the operation the pulse became poor, and it seemed unwise to attempt anything more. The patient recovered from the ether; but died about six or seven hours later.

As no autopsy could be secured in spite of our earnest efforts, I do not care to speculate upon the precise pathological conditions. The fact that a chronic suppuration existed enables one to picture the gradual encroachment of the disease upon the bony walls of the tympanum. It is, of course, impossible to say just where the eruption finally took place into the cranial cavity. As already suggested, the ways are numerous. At best the upper wall of the tympanic cavity, the tegmen tympani, is very thin, frequently of paper-like thinness; the bony wall of the aqueductus fallopii, enclosing the facial nerve, is no thicker, and the sheath of one of the vessels which enter the tympanum is always a possible means of transmission. Knapp has reported a case where the pus burrowed down the space in which is lodged the tensor tympani, and thence into the cranial cavity. Occasionally the bony septum between the middle ear and the carotid artery or the jugular vein is so thin that the slightest carious softening would perforate it. And there remains the lateral sinus, sometimes in close proximity to the tympanum. The labyrinth is, of course, only separated from the pus-producing cavity by the membrane of the fenestra rotunda.

The aphasia in this case is interesting. In the presence of well-marked aphasic symptoms, either amnesic or ataxic, there is encouragement to trephine and drain the abscess which may be supposed to occupy the appropriate centre. The diagnosis, however, between abscess and meningitis is obscure. It seems to the writer that the acuteness of the symptoms in this case, the high fever, and the fact that a chronic abscess could hardly have existed without causing some symptoms, make the diagnosis probably acute lepto meningitis. Particularly as the brain trouble so quickly followed the acute exacerbation of the long-continued tympanic suppuration. It would have been justifiable, however, to have trephined in this case, had it been seen before the condition became so serious. From the patient's sister later I learned that she had scarlet fever when about thirteen, and since that time, "more or less," earache, but never any severe pain. Frequently spoke of dizziness.

On November 6th (Wednesday) she was in good health. On November 7th some discharge of pus occurred in the night. On November 8th she was all right as the flow was more free, but at noon on the same day said she went home (from work) to syringe the ear. On the 9th spoke of dizziness and compared her head to a sawmill; and from this time on the progress of the disease has been described.

Case III.—A boy, age ten years, was referred to me October 5, 1895. There had been a suppurative discharge from the right ear for about three years. The pus was foul and occasionally bloody. No history of syphilis or tuberculosis.

A large polypoid mass was removed October 9th without particular trouble, and from that date careful antiseptic treatment carried out. I saw the patient about once in three days and always cleaned the ear thoroughly. I am confident that the details of the treatment were carefully observed. On November 9th he had so far improved that all home treatment was stopped. November 11th he was worse again and treatment resumed and kept up regularly but with little or no improvement. There was always a small amount of pus in the mouth of the Eustachian tube in spite of the most careful, local cleansing. On December 20th the membrana tympani seemed to be intact except for a small rounded perforation in the extreme anterior inferior quadrant. The boy could blow through the Eutachian tube and in this way force out a small amount of whitish pus. The drum membrane had of course lost its lustre and was retracted in its posterior segment. The walls of the meatus, next the drum membrane, partook of the general local condition. As the disease had shown no improvement for several days, and the condition of the drum membrane seemed to render any continuance of the similar treatment futile, the boy was etherized on December 20th and the malleus removed with the drum membrane in the usual manner, by cutting around the periphery of the membrane, cutting the tendon of the tensor tympani, the anterior and posterior ligaments of the malleus, severing some adhesions which had formed and the capsular ligament between the mallens and incus. A probe passed into the tympanum after the operation revealed roughened bone near the anterior surface of the promontory. The malleus was somewhat carious. The incus was not removed. Recovery from operation normal. During the next few days an abundant mass of granulations appeared in the middle ear, completely hiding the promontory. These were treated with solid nitrate of silver antiseptic applications used regularly, and the subsidence of

the disease during the next week was most gratifying. On January 1, 1896, there was a general improvement in the local condition, there being little pus, the granulations less abundant, and the promontory visible for the first time in several days. The general condition also markedly improved; the boy was brighter and heard better. On January 20th the ear was practically clean; dermatol, which had been blown in a week before, still remained dry. On March 23d his ear was reported dry and had been so since treatment was stopped. The hearing in this case could not be accurately tested, but the boy volunteered the information a few days after the operation, that he heard his teacher and the other boys better.

This case I have reported, not because it furnishes any remarkable phenomena, but because it shows what desirable results may be obtained in chronic suppurative disease of the middle ear, and because it forms an interesting supplement to Case II. And particularly do I report this because it is notorious that such diseases are often, very often, allowed to go untreated or treatment is relaxed after a few weeks have failed to effect a cure. A chronic suppuration of the middle ear is not a trivial, but a very serious disease. Where a carious process has become established, it is frequently steadily progressive to death. Of course the length of time before death depends upon the activity of the carious process and the direction it takes. The danger is appreciated by insurance companies, such persons not being acceptable risks. Cases II and III are similar; had Case II been treated earlier in life she would not have died of otitic brain disease. Had Case III been allowed to go without treatment he would have always had hanging over him the possibility of the same fatal termination. It will not do to say that death from this cause is so rare as to be of little practical importance. Between six-and seven-tenths per cent. of all deaths are due to otitic brain disease. This means a considerable number. It is too large to be ignored, particularly when we consider that most of the cases would be classed among the preventable diseases.

CLINICAL LECTURE.

DERMOID TUMORS.

By JOSEPH McFARLAND, M.D.,
OF PHILADELPHIA;
DEMONSTRATOR OF PATHOLOGICAL HISTOLOGY AND LECTURER ON BACTERIOLOGY IN THE UNIVERSITY OF PENNSYLVANIA.

Although in the early text-books of medicine and surgery occasional instances of the occurrence of dermoid tumors are mentioned, there seems to have been very little attention devoted to them until the time of Blumenbach (1785), who rejected the popular belief that they were punishments inflicted by God upon those who had been guilty of moral errors, and suggested that their formation was due to a definite *nisus formativus*. Baillie contributed information to the subject and refuted the old ideas by the discovery of an ovarian dermoid containing skin, hair, and bone in a little girl (a virgin) twelve years old. From this case Baillie was led to conclude that the genital organs of the human female were able in themselves, without fertilization, to generate and develop an embryo. A few years later Tumiati wrote upon dermoids, and regarded their formation as analogous to the double monsters. Still later, Meckel, in an interesting paper, concluded that these terratoma could originate from (1) conditions akin to pregnancy; (2) double monsters; and (3) the change of normal tissue into tissue of another kind in consequence of irritation. In 1854, Remak changed the views concerning these tumors by showing that they were congenital, and occurred at positions in which fetal clefts, fissures, or sinuses previously existed.

A dermoid tumor is one which contains mucous membrane, or skin. These tumors are generally cystic, and contain skin more often than mucous membrane, the skin being furnished with its various appendages. Although generally cystic, it is not unlikely that they originate as solid growths, and subsequently become cystic by the retention of sebaceous matter, the secretion of sweat glands, and the accumulation of exfoliated epithelium.

The skin, when present, does not cover the whole interior of the cyst, but, in the cases which I have examined, occurs in patches, more or less elevated, velvety in appearance, scattered upon the cyst walls. Beneath the skin not infrequently bone is present, occurring generally in flattened plates of irregular shape. Sometimes the bone is mandibular and contains sockets, from which teeth project through the epithelial covering into the cavity. The teeth are of various shapes; incisors, canines, and pre-molars occur. In the tumors which I have examined the teeth were without large roots, and resembled the milk teeth more than the permanent ones. Generally the teeth are well-formed and are white; sometimes they are deformed and discolored. The skin is generally furnished with an excessive number of sebaceous glands of large size. Sweat glands occur, but are less common. Typical hair follicles are often present, and bear hairs which are generally soft and downy but sometimes long and coarse. The hairs are nearly always blond. The hairs which occur in the tumors are always similar to those normal to the animal. In the negro, the hairs in the cyst are flattened and curly; in the sheep I have found small dermoids filled with soft wool; in the hog it is said that bristles occur, and Sutton states that the dermoids which occur in birds contain feathers. The skin patches are generally well supplied with villi, sometimes excessively so. Occasionally the skin covers smooth, rounded eminences suggesting mammary glands, and even provided with nipple-like projections. According to Sutton, these gland-like bodies are generally fatty in structure, but may be real mammary glands, provided with ducts passing through the nipple and secreting colustrum.

I have somewhere read, and am sorry that I cannot authenticate the statement with the reference, that nails and bones also occur in these cysts. The parts of the cyst-wall not covered with skin are generally covered by either squamous or columnar epithelium. The columnar epithelium is sometimes ciliated. In this epithelium, mucous glands may be present. The interior of the cyst is generally full of a mixed, smeary, granular material, which is made up of shed teeth, fallen or growing hair, epithelial cells and pearls, sebaceous matter, cholesterine and sweat.

We generally read about the epiblastic derivatives which occur in dermoids and give the tumors their name and it seems to be only within a recent period that it has been pointed out to us that the derivatives of the mesoblast and hypoblast are likewise represented. I have already pointed out that bone is present. Not infrequently cartilage is met with, not, however, as antecedent to bone, for the dermoid bones are generally membranous in origin. Striped and non-striated muscular tissues and much areolar tissue are also common, and are, of course, mesoblastic in origin. The hypoblast is probably represented by the columnar ciliated epithelium of the cyst and mucous glands which Wilms, to whose elaborate monograph I must refer later, regards as analogous to a reproductive tract, and as hypoblastic.

Cerebral tissue also occurs in dermoid tumors, especially in such as contain bone, and not infrequently scattered nerve cells resembling the motor nerve cells of the spinal cord, as well as nerve fibres, are found.

Before the time of Remak's paper, it was remarked that dermoid tumors occurred in the ovary and orbit with great frequency, but that certain parts of the body were seats of predilection does not seem to have been observed. Remak observed that they occurred by preference at positions in which the union of fetal clefts, fissures, or sinuses took place, and at which the skin could be included in the process of coalescence.

Continued observations upon the tumors has disclosed the fact that this is in great part true. We find them occurring in the great median fissures of the body, both anteriorly and posteriorly, in the mandibular fissure, orbital and naso-orbital fissure, bronchial clefts, in connection with the sutures of the brain case, and naso-pharynx. The fact, however, that they occur with great frequency in the ovary, occasionally in the testicle, and frequently in the abdominal and thoracic organs is opposed to the theory of Remak. Everyone knows that the ovary is the most frequent seat of occurrence. They have, however, been found in the pituitary body (Beck), in the olfactory bulb (Bonorden) in the esophagus (Hess), arch of the aorta (Stilling), lower lobe of the left lung (Cœlta), apex of the right lung (Salmonsen), and in the anterior surface of the heart (Pindus).

Meckel discovered a dermoid tumor of the diaphragm, from which twenty-one fragments of bone, four teeth, and considerable hair were removed. Ruysch found one in the omentum, Andral one in the mesentery, and Frankel one in the peritoneum. Bonfigli describes one which was adherent to the liver and stomach through an intermediate band; it contained teeth. Modelung described one from the kidney.

Clearly Remak's theory cannot be made to comprehend all these conditions. The only conclusion to which we can come is that it explains some, but not all cases, and that in consequence dermoid tumors may be several different, yet similar things. The old writers saw no difference between dermoid tumors and certain ectopic pregnancies, inasmuch as in them what were regarded as fetal elements were discovered. This led to the supposition that they were cases of imperfect conception, a theory which might readily apply to a tumor of the ovary, but could hardly be applicable to one of the orbit. The next supposition was that they were cases of *inclusio fetus in fetu*, and the next that they were analogous to the double monsters. It is probable that there is truth in all of these theories. Some of the tumors are certainly formed by the inclusion of fetal tissue during the arching-over processes of embryonal development. Tumors of this kind have been described as *sequestration dermoids*. They occur in the neighborhood of the fissures, which have already been pointed out. As the coalescence of the fetal parts is sometimes a little irregular, the tumors may not be situated exactly in the line of union, variation to one or the other side being rather common.

Similar tumors are formed by the persistence of fetal tubes, such as the thyro-lingual duct, the post-anal gut (as probably in the case just reported by Dr. Downes). These have been described as *tubulo-dermoids*. Both these forms are, of course, congenital, though the accumulation of materials in their interiors may not cause their size to be noticeable until late in life.

In classifying dermoid tumors, Sutton gives these two classes, then proceeds to describe those found in the ovary as *ovarian dermoids*. This arrangement makes his classification lack homogeniety, though it does not lessen its value. Indeed, how to approach the ovarian dermoids in any other manner than by placing them in a separate class is a question.

Ovarian dermoids are very common. Olshausen found that of 2275 ovarian tumors 80, *i.e.*, 4 per cent., were dermoids. They are more common on the right side than on the left. Mantel observed 191 cases, and found that 97 were on the right side, 67 on the left side, and 26 double-sided.

It is generally supposed that the embryonal cells of the developing fetus are in some manner "included" in the ovarian tissue, where they remain latent for a varying period, then take on a rapid development, with the production of tissues of the epiblastic type in irregular masses, *i.e.*, dermoid tumors. To me it is very difficult to understand just how these embryonal cells could be included in the ovarian tissue, and much more difficult to understand how they could remain latent for a period—as has really happened—of seventy years. Wilms doubts the congenital nature of the tumors, and in speaking of the theory under discussion, says that it serves to complicate matters, rather than to elucidate them.

If the tumors are not congenital, they must, of course, be developed in after life, and we must look in the tissues

in which they occur for the cells from which they can originate. Sutton suggests that the epithelial cells of the membrano granulosum are endowed with great vitality, and may be those whose energies are responsible for the development of the tumors and their contents. Wilms is, however, of a different opinion, and sees in the ovum itself a cell capable, when fertilized, of producing tissues of all kinds. For the elaboration of his theory, he brings forward the developmental cycle of the ovum itself, and calls particular attention to the extension of the polar granule. This is by embryologists regarded as a kind of male element in the female cell, which must be extended before the ovum can be ready for fertilization. If the powers of extrusion miscarries, and this granule remains within the ovum, Wilms sees no reason why parthenogenesis cannot take place, and an atypical and monstrous development of the ovum result with the production of a dermoid tumor instead of a fetus. Wilms supports his view by observations upon nineteen cases of ovarian dermoid tumors, which were subjected to a careful microscopic study. In each of them tissue derivatives of all three layers of the embryo were found—skin with hair, subaceous glands, sweat glands, and teeth, representing the epiblast; blood vessels, striped and unstriped muscle, and bone representing the mesoblast; and columnar ciliated epithelium in a rudimentary tube or sac, supposed to be analogous to the genitalia representing the hypoblast. So satisfied is Wilms that the ovarian dermoids originate in this way that he suggests abandoning the term dermoid, with the misconceptions attached to it, and using the term "rudimentary ovarian parasite" instead.

However, if the theory of Wilms be able to support itself against the currently accepted theories or not, it will only suffice to explain the ovarian tumors, and leaves us still in doubt concerning similar tumors in the lung, liver, kidney, and other internal organs. Unless these be congenital cases of *inclusio fetus in fetu*, or of inclusion of misplaced embryonal tissue in the developing organism, I am at a loss to account for them, and have no new theory to advance.

Dermoid tumors are benign in nature, as a rule, although their growth in some locations is accompanied by pain. A few rare cases are on record in which the epithelium in the tumors took on a carcinomatous development. The combination of dermoid and adenoma also occurs. Although benign, one case of seeming metastasis is reported by Emanuel, who observed the development of a dermoid tumor in the rectus muscle after removal of an ovarian dermoid.

Kollaczek has also reported a most extraordinary case of richly disseminated epithelial clumps over the entire peritoneum. In the centre of each nodule a hair was visible. Frankel has also seen a similar case.

The rupture of an ovarian dermoid, and of other dermoids, is always a serious matter, because of the irritating foreign matter which escapes into the peritoneum, and because of the danger of the occurrence of disseminated tumors as a result.

The diagnosis of the dermoid tumors is not always possible before removal, and sometimes difficult afterward, especially if hair, teeth, bone, and other easily recognized characteristics are absent. The contents of the cyst are partly characteristic, for scarcely any other lesion furnishes the smeary, turbid material which can be evacuated from a dermoid tumor. Examination of the cyst-wall by the microscope generally makes the condition plain by revealing epithelium and its appendages.

At times one of the most difficult determinations to make is the separation of the dermoid tumors and ectopic pregnancies. Wilms points out that this should offer few difficulties to the microscope, because of the invariable presence in the ectopics, and invariable absence in the dermoids, of placental or decidual tissues.

CLINICAL MEMORANDA.

A CASE OF GUNSHOT WOUND OF THE INTESTINE—RECOVERY WITHOUT OPERATION.

By J. P. TILLERY, M.D.,
of Coal Creek, Tenn.

July 30, 1893, I was called to see Effie L., aged six years, who was suffering from a gunshot wound inflicted by a 32-calibre Winchester rifle in the hands of her little brother. The bullet entered about 1½ in. to the right of the spine, on a level with the first or second lumbar vertebræ, and came out at the lower border of the left lung, in the axillary line.

Her home was two miles in the country and I arrived one hour after the accident. I found her suffering exquisite pain in the lower extremites. Stimulants were at once given to counteract shock, and an opiate to control the pain. I then ligated with a No. 12 silk ligature a piece of lung tissue 1¼ in. in length, which was protruding from the wound of exit, making slight traction to withdraw it sufficiently to avoid any infection from extraneous causes. Then, with a strip of iodoform gauze over the end of grooved director, I replaced the stump, leaving the gauze for capillary drainage. I then dressed the wound with gauze and cotton, throwing a broad bandage around the body to retain the dressing, and awaited developments. On the morning of the second day the temperature was 99⅗, and the dressing, being soiled, was changed and a fresh piece of gauze inserted in the wound. The child still complained of pain in the lower extremities, with very limited motion, which was due, I think, to concussion of the cord; the ball, in my judgment, having struck the body of the vertebra. Her symptoms were uneventful until the morning of the fourth day. When the dressing was changed it was found that the ligature had come off the stump, and, with the drainage gauze, was found in the dressing, and protruding from the wound to the extent of an inch was an intestinal worm (Lumbricoid). Taking hold of this unwelcome visitor I removed it, and found it to be about five inches in length. This was the first indication of injury to the bowels, there having been no indication of peritonitis. However, there had been some tympanitis from the second day.

The seriousness of the case was at once announced to the family and the possibility of an operation suggested. Dr. L. Jones Price of Knoxville, was called in consulta-

tion, and there still being no indications of peritonitis fourteen hours after discovering the worm, we decided to still await developments.

The wound was kept open until the eighth day, when it was found impossible to introduce the gauze. Her temperature was now normal and her recovery assured. The pain gradually subsiding in the lower limbs, after about six weeks she was able to walk, and up to this time has had no further trouble.

The question naturally arises in my mind as to what part of the intestinal canal was injured, and why did she escape peritonitis?

DR. GIBNEY'S METHOD OF TREATING SPRAINED ANKLE, WITH REPORT OF SEVEN CASES,[1]

By F. D. REESE, M.D.,
of Cortland, N. Y.

While persuing the pages of the *New York Medical Journal* of February 16, 1895, I came across an article entitled: "Sprained Ankle—A Treatment that Requires no Loss of Time; Requires no Crutches, and is Not Attended with any Impairment of Function."

The article was written by Dr. Gibney of New York. This method of treatment of sprained ankle, with rubber adhesive plaster, I have called by his name, although he claims no priority, but says Dr. Cotterell of London, used a similar process.

For a sprain about the external malleolus, take a roll of the best rubber adhesive plaster, about 1 inch wide. Begin at the outer border of foot, near the little toe, and carry it around the heel to a corresponding point on the inside of the foot. The next strip is applied vertically, and begins at the juncture of the lower and middle third of leg, and passes down along the tendo-Achillis around the heel and up the leg to a point opposite the place of beginning. The rest of the strips are applied in the same manner as these two, overlapping each other about one-third, until the ankle and instep are all covered, except one inch in the median line. This is left to guard against any possibility of cutting off the circulation.

Dr. Gibney says: "If the sprain involves the tarsal joint itself, or mid-tarsal joint, straps should be applied as follows: The first one begins on the inner side of the heel, passes back of the heel, below the external malleolus, over the dorsum of the foot, and terminates just below the ball of the great toe. The second one is started just under the external malleolus, passes back of the heel, over front of the foot, and terminates just under the outer side of the foot, near the small toe;" but this I would hardly deem necessary if the straps are applied as described, bringing the ends of the plaster within one inch of each other.

You can readily see that these strips of plaster become a closely interwoven and tight-fitting splint, that restricts motion, sustains the injured ligaments, and tendons, and prevents effusion. This treatment impressed me as being the ideal one, and I resolved to give it a practical test.

[1] Read before the Cortland County Medical Society, March 12, 1896.

The history of seven cases which have been treated by this method are presented, after which I leave it with the reader to decide whether the results from Dr. Gibney's method of treatment of sprained ankle justify the title of his article.

Case I.—Charles R., aged twenty; sprained his right ankle as the result of a misstep while working in the woods, December, 1894. He had recovered from the more acute symptoms and pain when he came to my office, March 13, 1895, but could not then step squarely on his foot, and was compelled to support himself with two canes. Examining the ankle I found a subacute inflammation and tenderness on pressure around the external malleolus, and over the tarsal bones. Adduction and flexion of the foot cause more or less pain, and he said (which was evident) that he was unable to do his work. I applied the straps as described, and he was able, immediately, to abandon the canes, and walked with but a slight hitch in his gait. He was directed to wear the straps until they came off, if they continued to afford relief. Some months later he said he wore the straps for six weeks, and, that as far as he could see, he had made a perfect recovery.

Case II.—Mrs. L., aged thirty-six, fell from her bicycle and sprained her left ankle, April 20, 1895. I saw her at her home the same afternoon. Around the external malleolus and over tarsal bones, the tissues were swollen, and there was extravasation of blood. Motion was limited and pain extreme. I applied the straps, and she was able to take a few steps around the room. Some weeks later she reported that she had suffered a good deal of pain for about a week, after which she gained rapidly and was well at the end of three weeks.

Case III.—Mr. R., minister, aged fifty, slipped and sprained his left ankle June 26, 1895. His wife applied hot fomentations until the day following, when I was called to see him. I found him in bed and he declared to me, "It is a physical impossibility to walk." The tissues were slightly swollen, around and under the external malleolus, with some ecchymosis. There was great tenderness upon pressure, and limited motion. Applied the straps and patient was able to walk around the room with ease. The day following, he walked to a near neighbor's. This was on Wednesday, and the following Sunday, he walked twice to church and preached at both services. July 3d, changed the straps. There was some tenderness, and tissues were black and blue. On July 16th, discharged the patient.

Case IV.—Mr. S., aged sixty-five, broommaker, came to my office on crutches, June 27, 1895, and gave the following history:

Fell off the porch, eight weeks before, and sprained, as he supposed, his left ankle. On examination I found he had not only sprained the ankle, but had fractured the fibula, low down. I applied the straps, which gave him a great deal of comfort as far as the ankle was concerned. Reapplied the straps July 13th, when there was less swelling, and the callous at the break was more easily felt. He was able to walk with one cane; from this time his recovery was uninterrupted.

Case V.—Mr. B., aged thirty-three, came to my office

on crutches. June 28, 1895, suffering from a sprain of left ankle, which occurred two days previous. The ankle was badly swollen around external malleolus, and instep ecchymotic. Manipulation caused pain, and the foot was restricted in its movement. Applied the straps, which gave immediately relief, and he was able to step on the foot. Reapplied straps July 2d, and discharged the case, well, July 19th.

Case VI.—Mr. H., aged thirty-one, slipped and sprained his right ankle, August 19, 1895. He called at my office the 20th, was then suffering great pain during locomotion. Found the ankle swollen about external malleolus, but no extravasation of blood. Applied the straps and the patient experienced immediate relief. He lost no time, but worked at his trade, which was that of molder. August 27th, I discharged the patient, but he was to wear the straps a few days longer.

Case VII.—Miss K., aged twenty-four, was brought to my office July 17, 1895. History as follows: She had fallen and sprained the right ankle and tarsal joints. She could not step on the foot, and suffered a great deal of pain from it. The movements of abduction, flexion and extension were restricted. The tissues were slightly swollen over these joints. Applied the straps, but she was unable to stand. (I think this was in part due to fear.) She was greatly relieved of pain. July 22d, five days after, she removed the dressing, at the suggestion of a friend, believing the parts should be bathed. July 23d, she suffered so much pain that she sent for me, and I reapplied the straps, which gave her instant relief. Her recovery was uninterrupted and she returned to her work, fourteen days after the first application of the straps.

MEDICAL PROGRESS.

A Sympathetic Ganglion in the Human Ovary.—As the result of an histologic study Winterhalter (*Archiv für Gynækologie*, B. LI, H. 1, p. 49) has succeeded in finding in the zona vasculosa of the human ovary ganglion-cells of roundish or polygonal form, without demonstrable nuclei, provided with numerous short and long, thick, and simple processes, consisting of a single medullated nerve-fibre, corresponding in all other respects to the non-medullated fibres found in the ovary. The cell-processes vary in number, and may arise from the entire circumference of the cell, from only one side or from opposite sides; they vary in thickness individually, some continuing without change in calibre, others growing thinner as they proceed and finally breaking up into several fibres; some surround the blood-vessels concentrically. The cells lying in the vascular layer close to the large nerve-trunks send processes to and receive others from these trunks. The processes of all of the ganglion-cells terminate within the zona vasculosa; none could be traced into the follicular layer, but it is not impossible that they enter this layer with the blood-vessels, as many fibres, whose continuation could not be followed, accompanied the vessels. No ganglion-cells could be found in the follicular layer. The hypothesis is proposed that the irritation of the ripening follicle is conveyed to the surrounding nerve-fibres to the processes of the ganglion-cells in the vascular layer, wherein it accumulates until it reaches sufficient intensity to give rise through other nerve-processes to a motor impulse, resulting in the vascular changes characteristic of menstruation.

The Sterilization of Catgut.—At a recent meeting of the Berlin Medical Society Saul (*Wiener klinische Rundschau*, 1896, No. 9, p. 154) described a method of sterilizing catgut by means of boiling alcohol, that he has found efficacious and satisfactory. A combination of alcohol 80 parts, carbolic acid 5 parts, and water 15 parts, effected the purpose best. Hofmeister (*Centralblatt für Chirurgie*, 1896, No. 9, p. 193) has employed the method of Saul, but failed to secure satisfactory results. His own method consists in first hardening the crude catgut, wound upon rolls, by immersion for twenty-four hours in a four per cent. solution of formalin; then boiling in water for ten minutes, and subsequent hardening and preservation in alcohol, to which have been added five per cent. of glycerin and one-tenth per cent. of mercuric chlorid.

THERAPEUTIC NOTES.

Quinine-Intoxication.—Murri (*Deutsche medicinische Wochenschrift*, 1896, Nos. 8, 9) reports the case of a girl, nineteen years old, who was seized with malarial fever which apparently yielded to treatment with quinine, but recurred. The paroxysms were repeated at irregular intervals, and from time to time quinine was taken. On one occasion an attack followed shortly after a dose of quinine, but the chill was more pronounced; vomiting also occurred; the urine presented an unusual dark-brown color, and on the following day the skin was discolored yellow. Matters thus continued for several months, the administration of even 7½ grains of quinine giving rise to toxic symptoms. On examination the spleen was found to be enlarged and hard. During a febrile paroxysm the urine contained peptone, serum-albumin, globulin, hemoglobulin, and urobilin, but no biliary pigment. Microscopic examination disclosed the presence of hyaline tube casts, renal epithelium, and lucocytes. Repeated examination of the blood showed a slight diminution in the number of red blood corpuscles, but no malarial parasites at any time. After the paroxysm urobilin and bilirubin were found in the blood. It was noted that the attack was repeated after the patient had eaten, and the digestive functions were deranged. In later attacks the liver was also observed to be enlarged. Under treatment with iron and rest in bed, the condition of the patient greatly improved. To confirm the opinion formed as to the relation of some of the attacks to the administration of quinine, this drug was on a number of occasions given, with the result of inducing nausea, vomiting, epigastric pain, and tenderness, a sense of coldness, redness of the face, hyperemia of the conjunctivæ, cephalalgia, elevation of temperature, acceleration of pulse and respiration, increased size of the spleen, tenderness over the liver, and changes in the urine and in the blood. The patient ultimately recovered her previous state of health, although it was possible, with the precision of a laboratory experiment, to reproduce the symptoms from which she had long suffered.

The Medical News.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to The Medical News will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 Fifth Avenue (corner of 18th St.), New York.

SATURDAY, APRIL 18, 1896.

THE AMERICAN ACADEMY OF MEDICINE, AND MEDICAL TEACHING.

The American Academy of Medicine will hold its next meeting in Atlanta, Ga., May 2d and 4th. The influence of this organization is far-reaching and powerful. And since it has turned its attention from the theoretical subjects, which engrossed its deliberations in its earlier history, to the vital practical problems of the day, the value of its work cannot be overestimated. The wisdom of concentrating all the business of each meeting upon one important economic subject is apparent. Last year the subject of discussion was the Hospital and Dispensary Abuse and the wide problems envolved in the general relation of the profession and the community to the dependent classes. The accumulated statistics then presented, and the abuses there ventilated, have permeated thought and given direction to reformatory measures that will gradually work out, it is believed, the practical solution of these difficulties. At the meeting next month the question for discussion is one of great and vital importance. The program embodies a discussion, by prominent medical teachers from all sections of the country, upon Methods of Medical Teaching.

Probably no subject connected with the profession demands a more thorough shaking up than this. It is full of the dry bones of tradition and custom, whose origin dates from the dark ages, when books were unknown and knowledge passed only by word of mouth. The field of knowledge was limited, and the means for personal investigation did not exist. Now the field is boundless, and the authorities and instruments for personal investigation are in every student's hands.

Formerly the memory was about the only faculty that was cultivated. And the isolated facts that were crammed into the student's mind and held, as it were, by brute force of memory is wearisome to recall.

Memory has its place and it is an important one. The power to grasp and comprehend facts, however, is the foundation of all knowledge. To retain them in the mind is important. But the faculty of utilizing those facts, of putting two and two together, and reaching the logical conclusion is the distinctive attribute of the human mind. In the processes of acquiring a medical education these faculties of the mind—the perception and the reason—can be disciplined and developed as well as in the pursuit of the academic degree and should receive vastly more attention.

This is the great principle that underlies all education. It is candidly and frankly recognized by medical teachers, but how it can be applied in our medical schools, to all the detail of the various branches, is the problem which our leaders of thought must work out to a practical conclusion. This is the question upon which we are looking to the deliberations of the Academy to shed a flood of light.

IMMORAL INFECTION IN HOSPITAL WARDS.

Medicine is such an engrossing profession, that the physician is apt to overlook many matters and many opportunities which lie just outside his routine work, but which cross his path daily. We question seriously the propriety of the physician arrogating to himself the duties of the clergyman, as some well-meaning persons believe he should, yet no conscientious practitioner can be oblivious to the fact that his indirect influence for good or evil is tremendous. We wish, at present, to call

attention to only one phase of this moral obligation in connection with hospital service.

Passing through the female wards of almost any hospital, one will see a plentiful representation of prostitutes, from the blear-eyed hag, in whom the ravages of alcohol and syphilis have obliterated all that is attractive and womanly, to the girl just entering on a career of shame, who has learned the art of making the best of each grace and charm without having, as yet, acquired a repulsive boldness. Some of these women are plainly in need of medical aid, suffering from venereal disease, from various pelvic disorders, afflicted with some general disease, or awaiting confinement. Others, again, show no more evidence of serious illness than do the occupants of some of the private rooms, who spend their lives in the pursuit of relief from ailments due to imagination and idleness. Why is it that a certain class of quasi-invalid prostitutes seek the hospital? Partly because—comparatively few of the women to whom we refer being city charges—a reasonable board rate affords medical attendance and nursing, with many little luxuries and an opportunity for rest and idleness; partly because houses of prostitution recruit their forces, to a large extent, from the innocent but frivolous and shallow girls to be found in public hospitals. Such girls look forward to the return of health with anxiety rather than pleasure. Discharge from the hospital means, to them, to be thrown out into the world without money, often without proper clothing, usually without assurance of work. What wonder that such girls are flattered by the attention of prostitutes, whose soft hands, jewels, fine attire, and imitation of good breeding, all suggest to the ignorant that they belong to a real lady? What wonder that too many follow the line of least resistance, away from a life of toil to the physical comforts and idleness of the brothel?

The evil to which we have referred is as real as though it was caused by a germ, its suffering is as great as though it were felt in physical centres rather than by the mind. Leaving aside the strictly religious and moral aspect of the question, it is as much the duty of a physician to prevent the misery entailed by a life of prostitution as to adopt sanitary measures against the spread of scarlet fever or diphtheria through the hospital. And, to complete the analogy, prophylaxis must be along the same line—isolation of the infected ones, so that they may not contaminate others by their effluvia.

GENERAL SURGERY.

A CRITICAL RESUME OF RECENT PROGRESS IN CEREBRAL SURGERY.

The discussion on cerebral surgery at the recent meeting of the New York State Society does not offer much encouragement to the enthusiast in this branch of surgery. The conclusions reached must be of value, as they expressed the deliberate opinion of several prominent neurologists who have had a large experience in this class of cases. It cannot be truthfully charged that surgeons have ever been overenthusiastic about operations on the brain. Ten years ago it was expected that the advances in cerebral localization would open up an avenue for successful surgical interference on many cases of cerebral disease. It must be acknowledged, however, that this expectation has not been realized. It is perhaps as well that the views of the neurologists referred to, were somewhat discouraging, for it will tend to limit operative interference in questionable cases, and the inference must naturally be drawn that in the future, cases for cranial operation, especially when for the cure of epilepsy, will be more carefully selected than has been the custom during the past few years. The difficulties in the way of correct diagnosis ought to stimulate the diagnostician to a more careful observation, and a more accurate classification of the characteristic symptoms of every case, so that he may be able to reach a reasonably certain decision as to the possibility of relief by means of operation. At the present time it certainly appears as if but a small percentage of patients, who suffer from cerebral disease, can be relieved by surgical interference. The most favorable results have been obtained in abscesses, due to ear disease, and in sinus thromboses. It is true that some brilliant cures have followed operations for tumors, or for the relief of Jacksonian epilepsy when due to traumatism, but such results are exceptional. Reports of cases both of failure and of success, are slowly accumulating, and as the number increases, the prognosis of such operations must at least become more

accurate, if not more favorable. In a department of surgery where the cases can be counted by the score only, instead of by the thousand, as in some specialties, the history of even a single case must be of interest, and often of great value.

The uncertainty of diagnosis is only one reason why results are apt to be unsatisfactory. There are three more potent reasons: first, the character of the lesion; second, its inaccessibility; and third, the impossibility of its removal without the substitution in its place of other lesions of equal or greater severity, Many cerebral tumors are either malignant or tubercular. The difficulties attending the removal of cancer in other regions, apply with still greater force to cerebral growths of this character. The same difficulties, though to a less degree, apply to operations on tubercular tumors. Since the appearance, in 1889, of Bergmann's monograph on tubercular tumors of the brain, operation upon these growths, has not been regarded with much favor, by either neurologists or surgeons. His objections to surgical interference in this class of cases were, first, that following the operation, there was apt to be extension of the tubercular process to the coverings of the brain, resulting in a fatal tubercular meningitis, and second, that removal of the growth was apt to be incomplete, and that recurrence was almost certain and generally rapid. Recent experiences have, however, somewhat modified this unfavorable view. A number of apparent cures have resulted. In a recent article by Krönlein, fifteen cases of operation are reported. Four of these patients were permanently cured, and two were temporarily improved. The mortality was great, seven having died as the result of the operation, though in four of these, the tumor had not been found by the surgeon. It must be granted that there are cases of cerebral tuberculosis which should be subjected to operative interference. They are, however, exceptional, as either general tubercular infection or advanced disease of any other single organ must contra-indicate operation. The same is true of malignant growths. A few successful cases have been reported, but we cannot expect much progress to be made in this direction. Often, however, the nature of the tumor cannot be known and if from the symptoms it can be judged that there is a probability of its removal by operation, an exploratory opening in the skull is certainly justifiable. The danger of this procedure is slight, and a benign tumor may be exposed.

The inaccessibility of the growth will always prove a great barrier to the successful removal of brain tumors. Tumors at the base of the brain or buried deeply beneath the cortex, will always defy the operator. The damage which necessarily must be done to the cerebral tissue in order to reach them, is the factor that nullifies the operation.

A very complete account of all operations for tumors of the brain has been made by Starr. Up to 1896, he has collected 162 cases. In 48, the tumor was not found by the operator. In 7 cases it was found, but could not be removed. In 107 cases the tumor was found and removed; 72 of these patients recovered, and 35 died. Considering the hopeless nature of such cases, this mortality is certainly not excessive.

The results of operation for the cure of epilepsy have been very disappointing. In comparatively few cases is resort to surgery justifiable. It is exceptional that autopsy on such cases reveals any gross lesion within the cranium. And a favorable result is to be expected in such cases only where there is a visible lesion, so situated that it can be easily reached and safely removed. The most favorable results are to be expected in cases where there is an irritative lesion pressing on the cortex of the brain. If there is a reasonable chance that such a lesion exists, operation is demanded. For example, when the convulsions follow a traumatism, the irritant being a depression of bone, a thickened dura, an organized blood clot, a cyst, or an abscess, the chances of cure are good, provided that years have not elapsed between the time of injury and of operation. In cases of Jacksonian epilepsy without a traumatic history, the outlook is less favorable. In many of these, the lesion is one that cannot be removed by operation.

The excision of that part of the cortex which governs the affected muscles but rarely gives permanent relief. In its place there forms a cicatrix which remains as a source of irritation; indeed, after many cerebral operations, this cicatricial tissue will prevent a permanent cure. The

new tissue may not at first act as an irritant, and on this account many of the reports of "cure by operation" are valueless, inasmuch as sufficient time has not elapsed after the operation to fairly decide whether or not a cure has been effected. No definite conclusion can be drawn until a year at least has elapsed. It must not be overlooked, however, that in certain cases where radical operation is impossible it is justifiable to make an opening in the skull for the relief of intra-cranial pressure. Such a safety valve will often temporarily relieve the symptoms, and may even permanently mitigate the violence of future attacks.

The operative technic of cranial surgery varies somewhat, according to the training, mechanical skill, and experience of the surgeon. On one point all are agreed, *i.e.*, the vital importance of strict asepsis or antisepsis. Various methods are employed for exposing the interior of the cranium. The older method, according to which one or more buttons of bone are removed by the trephine and the opening enlarged by the *rongeur* bone forceps is still frequently employed. If a large opening is required it can be made with greater rapidity, according to Horsley's method, by means of the ordinary amputating saw and his massive bone forceps. The employment of either of these methods, however, prevents the replacement of the bone. If it is considered undesirable to leave a permanent gap in the skull—and this opinion is entertained by the majority of surgeons—the flap method must be employed. The curved incision in the bone can be made by either the chisel or a saw worked by an electro-motor and, the base being broken, a window of the desired size is made, through which the necessary inspection and manipulations can be accomplished, after which the flap is replaced. If chisels are used, hard blows must not be struck by the mallet, as serious results have been attributed to its impact. Cases have been reported where considerable shock to the respiratory and circulatory centres has been thus produced, and where subdural hemorrhages have resulted. If the saw be employed this concussion is avoided, and the section is more rapidly made, but in spite of every precaution the best saws will occasionally fail at the most critical moment, and there is also the disadvantage that it is difficult to perfectly control its movements and hence injury to the dura and brain is apt to occur. Until recently, the saws employed have been very thin, so that it has been almost impossible to see the bottom of their groove and to ascertain what depth has been reached. The blades are now made thicker, and this improvement ought to lessen the risk to the brain and its membranes. In spite, however, of many ingenious devices of this nature, the use of the saw or burr is not altogether satisfactory. If one or other is to be employed, it is probably wiser to make with it a partial section only of the skull, and complete it with light blows of the chisel. A new instrument, combining saw and forceps, has recently been devised by Dahlgren of Upsala. He claims that he can cut out a large flap in *four* minutes. It is frequently found, however, that instruments will perform such perfect work in the hands of their inventors only, and the description of these forceps would not incline one to believe in the rapidity of action claimed by its originator. Horsley, whose experience is very large and whose rotating saw is one of the best, has abandoned its use and disapproves of the flap operation, as he see no special disadvantage in leaving a permanent opening in the skull. It is certain, indeed, that patients who have large openings in their skulls suffer no inconvenience from the bony defect; still it seems wiser to restore the continuity of the cranial vault, provided this can be accomplished without subjecting the patient to additional risk. The popularity of the flap operation is increasing, but as yet, there are imperfections in the technic of this method. A larger experience is needed before it can be definitely decided which of the two plans gives the most satisfactory results.

Andrew J. McCosh, M.D.

ECHOES AND NEWS.

The third of the series of Cartwright Lectures of the College of Physicians and Surgeons (Medical Department of Columbia University, New York) will be given in the hall of the Academy of Medicine, No. 17 West Forty-third street, New York, on Wednesday, 22d, at 8.15 P.M., by George S. Huntington, A.M., M.D., Professor of Anatomy in Columbia University. Third lecture: "Morphology of the Bronchial System and its Relation to the Pulmonary Vascular Supply in Mammalia."

It is with pleasure we learn through an English exchange that "a sum of £2300 has been received by the Huxley Memorial General Committee. This will be sufficent for the erection of the statue of the great scientist in the Natural History Museum, and for the establishment of a medal at the Royal College of Science."

Dr. Francis J. Quinlan has been appointed laryngologist and rhinologist to St. Vincent's Hospital, in New York City.

The sale of cigarettes or material for making them is now prohibited in the State of Iowa by an act of its late legislature.

It is reported that measles have invaded the White House, and that at least one of the President's little daughters is suffering from this disease.

One of the New York theatres is shortly to produce an American comedy under the title of "A Fashionable Physician."

New possibilities in the use of the Röntgen rays have been discovered by Dr. Frenzel of Berlin. Twelve sheets of bromide of silver paper laid one upon the other were placed in the holder and the skiagraph of a frog taken. The image was equally well defined on each sheet.

Leprosy has broken out in the Russian Baltic provinces with something of the virulence it possessed in the Middle Ages. Several hundred persons are said to be afflicted with the disease, and the Livonian Diet has just taken measures for isolating them at the cost of the state.

The health officers of the western cities evidently do not hold the virtues of "Divine Healer" Schrader in very high esteem. He was banished from Cincinnati, arrested in Newport, and when last heard from, other places were waving him off with inhospitable gestures.

The lay press has recently suggested, with more good judgment than is usual with them when discussing medical matters, the use of cold water and massage for congestive headaches. In deference to a time-honored respect for prophylactic methods, we beg to amend the above by suggesting that a strict adherence to cold water internally may render the massage unnecessary.

Under the administration of the newly enacted law in New York, known as the Raines bill, the druggists are exceedingly cautious in dispensing liquor, even upon a physician's prescription, unless his standing is known to them. It is also probable that the products of the soda fountains will be less contaminated with alcoholics in future.

A portable crematory for military purposes has been invented by a Polish engineer. It has the appearance of the army baking oven, but is much higher and heavier, and is drawn by eight horses. It is intended for the disposal of the bodies of soldiers killed in battle, so as to avoid the danger of epidemics from the burial of great numbers of men. Each German army corps, it is said, will be equipped with one.

The National House of Representatives has passed a bill taxing the manufacture and sale of an article of diet known as "filled cheese." This is said to be a cheap, but not unwholesome, substitute for ordinary cream cheese, and is made from skimmed milk and lard oil.

Dr. Alvah H. Doty, health officer of the Port of New York, has just returned from a trip through Mexico, and a visit to Havana. In the latter place, he found very unsanitary conditions existing, and saw a moderate number of cases of yellow fever. From present indications he expects these to increase as the season advances, and as a matter of precaution, all passengers who do not bring a certificate from Dr. Burgess, the U. S. Marine Hospital Inspector, residing in that city, will be held after May 1st at the New York quarantine station, until five days have elapsed after their departure from Cuba.

A bill before the National House of Representatives, providing for the adoption of the metric system of weights and measures in the various departments of the United States Government, was passed last week, but later reconsidered and finally referred back to a committee. It is said that the intelligent members of the House strongly favor the measure, and there is little doubt of its final adoption.

A dozen or more of Cincinnati's most eminent physicians and surgeons have inaugurated a movement for establishing a "Doctors' Headquarters." The offices of the promotors will be located therein, and a telephone on every floor, connecting with each office, serves the purpose of all. The prime object of the plan is to provide means whereby an urgent call may receive immediate attention.

The New Orleans *Med. and Surg. Journal* for April, after commenting upon the recent editorial in the Medical News discussing the care of leprosy in New York, and the country generally, says: "The State of Louisiana has attempted legislation in the matter, and the efforts at segregation are being watched with much interest. We have much to do at home in the matter, before the wheels of a national government can be even got ready to move. The medical profession of the State should make the effort, before enforced Federal legislation shows us how to do it."

At the Am Urban Hospital in Berlin 411 diphtheria patients were treated in 1894–95, 255 of whom were discharged cured. Of 245 treated with serum, 28 per cent. died, while among the 146 who were treated otherwise the mortality was 42 per cent.; 53.2 of the serum cases were serious, 23.7 severe, and the rest slight. No evil effects were observed to follow the use of the serum, and its effectiveness was proportionate to the earliness of its application and the strength of the first doses. The hospital authorities infer from this that it is not an infallible, but a highly valuable remedy.

The celebrated Professor Langerhaus, Medical Director of the Moabit Hospital, startled Berlin by causing the following announcement to be published in the papers: "Our darling Ernest, in perfect health, aged twenty-one months,

died suddenly in consequence of an injection of Dr. Behring's diphtheria serum." Immediately after the death of his son, Professor Langerhaus sealed the vial containing the serum used in giving the alleged fatal injection, that it might be examined by the local authorities.

The professor states that his son was in normal health, and was inoculated with the serum merely as a precaution, a housemaid in the family having diphtheria, and he having lost two children in 1895 from the same disease. The autopsy held by the public authorities upon the body of the infant left the charge that he was poisoned by an injection of Dr. Behring's diphtheria serum unproved.

Attention is directed in the current number of *The Practitioner* (London), to the decadence in the medical department of the British army, due to a lack of attraction in the service. Evidently much the same conditions exist as those to which we recently called attention in the medical corps of the U. S. Navy. Unless the present reluctance on the part of both nations to recognize the real worth and dignity of the medical staffs by promotion to rank and pay in better accord with the qualifications demanded, a manifest weakness, if not a fatal palsy, in this important arm of the service must inevitably follow.

It has been determined by experiment that the typhoid bacilli will exist in oysters for at least a month after infection, and probably actually multiply both in the body and juice of this popular article of diet.

A recent report made and signed by the superintendents of six London hospitals upon the use of antitoxin in 2182 cases of diphtheria contains the following conclusions: (1) "A great reduction in the mortality of cases brought under treatment on the first and second day of illness. (2) The lowering of the combined general mortality to a point below that of any former year. (3) The still more remarkable reduction in the mortality of the laryngeal cases. (4) The uniform improvement in the results of tracheotomy at each separate hospital. (5) The beneficial effects produced on the clinical course of the disease."

Professor Haffine has returned to India, and will continue his anti-cholera inoculations. At the suggestion of the India Tea Association, the coolies at Calcutta, who enlist for work in the gardens, will be subjected to his method.

The Royal Commission on Vaccination of Great Britain is holding weekly meetings at present, with a hope of drawing up and presenting to Parliament during its present session a final report including evidences obtained from the present outbreak of smallpox at Gloucester. Dr. Sidney Coupland has been commissioned by it to visit Gloucester and report upon the epidemic and its causes.

The U. S. Navy Department at Washington received last week a statement from a naval surgeon on duty at Hong Kong, China, that the black plague had broken out at that port, but for commercial reasons the municipal government endeavored to keep the fact secret. Orders have been given to guard against importation of the disease at San Francisco. This acute infectious disease, if we may judge from historical accounts of its first invasions of Europe in 1347, and again in 1665, is a veritable "Angel of Death" sparing neither bird, beast, nor man. During the former epidemic, Venice alone lost 100,000, or seven-tenths of her population; in Genoa scarcely one-seventh of the inhabitants survived. As a result of the last visitation in London there remain to this day many mementos of the plague in the shape of green plots in the centre of the most populated districts, marking the spots where thousands of corpses were buried in deep pits with tons of quicklime.

The trustees of the Jefferson Medical College of Philadelphia have purchased a large property at the corner of Tenth and Walnut streets, immediately adjoining the present college and hospital buildings, on which they intend erecting a new hospital. The present hospital building is inadequate because of the great number of patients presenting themselves for treatment, the situation of the hospital, in the centre of the city, bringing many poor to its doors. It is said that von Esmarch, on visiting the Jefferson hospital some years ago, remarked that other institutions had finer buildings, but that this hospital was the greatest working hospital he had seen in America. The plans of the new building are such as to give not only satisfactory opportunities for treating patients, but also for teaching clinical medicine. Immediately on the completion of the new hospital, the present college building will be torn down and rebuilt in accordance with the most recent methods of teaching practical medicine.

The following medical societies and associations will meet during the month of May: American Academy of Medicine in Atlanta, Ga., 2d and 4th; Association of American Physicians in Washington, D. C., 2d and 4th; American Gynecological Society, in New York, 26th, 27th, and 28th; American Medical Association in Atlanta, Ga., 5th to 8th; American Laryngological Association in Pittsburgh, Pa., 14th to 16th; American Orthopedic Association in Buffalo, N. Y., 18th to 20th; The Association of Military Surgeons of the United States in Philadelphia, Pa., 12th to 14th; American Climatological Association in Lakewood, N. J., 12th and 13th; American Pediatric Society in Montreal, Can., ——; Connecticut Medical Society in New Haven, 27th and 28th; Illinois State Medical Society in Ottawa, 19th to 21st; Kansas Medical Society in Topeka ——; Louisiana State Medical Society in New Orleans, 5th; Missouri State Medical Association in Sedalia, 19th to 21st; Medical Society State of North Carolina in Winston, 12th; Ohio State Medical Society in Columbus, 27th to 29th; State Medical Society of Pennsylvania in Harrisburg, 20th; Washington State Medical Society in Tacoma, 19th to 21st.

Dr. Theodore B. Hyslop of St. Mary's Hospital Medical School, London, in discussing the mental propensities that appear late in life, remarks that "the main features of senility tend to group themselves into three main types, which have been termed respectively, dotage, anecdotage, and *table d'hôte*-age."

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

General Meeting, April 2, 1896.

JOSEPH D. BRYANT, M.D., PRESIDENT.

THE CLINICAL ASPECTS OF GLYCOSURIA.

DR. WILLIAM H. DRAPER read a paper with this title. He said that clinically glycosuria, like albuminuria, is a symptom, and hence is of variable significance. There was a great difference in the personal appearance of glycosurics, as well as a great variety in the derangements of health for which they seek relief, and in very many instances the glycosuria was first discovered by some specialist who has been consulted by them. No theory seems adequate to explain all the cases of glycosuria coming under observation. Physiological chemistry had demonstrated that glycogenesis was sometimes the result of an interruption in the metabolism of the carbohydrates, and sometimes due to a derangement in the metabolism of the nitrogenous elements of food. This fact, together with the knowledge that it developed after certain diseases and traumatisms of the nervous system, constituted about all our information of the pathology of glycosuria. We recognized clinically two varieties: (1) a variety in which it is apparently the result of imperfect combustion of the carbohydrates of food into their ultimate constituents, and in which the withdrawal of the carbohydrates and the substitution of animal food causes a disappearance of sugar from the urine; and (2) a variety in which the glycosuria persists even after the withdrawal of carbohydrates from the diet. The first form is mild and more or less controllable, while the second is grave and progressive. While it had been generally accepted by the profession that glycosuria was intimately associated with the glycogenic function of the liver, Pavy had always stoutly maintained that the liver was a sugar-destroying, and not a sugar-forming organ. From a chemical point of view, glycosuria is essentially a disease of suboxidation, but the cause of this suboxidation still remains shrouded in obscurity. From clinical observation, it would appear that in a certain small proportion of cases saccharin diabetes is due to direct heredity, and that, in a much larger number of cases, the disorder may be traced to an inherited constitutional incapacity for the easy and complete digestion of the carbohydrates—the starches and sugars. It was a matter of common bedside observation that gouty individuals found great difficulty in digesting any large quantity of sugar or starch food; and in view of the now very generally accepted belief that lithemic gout is a congener of glycosuria, this fact is significant. The speaker said that personally he had very frequently noticed the occurrence of glycosuria in gouty families. This feeble power for the digestion of starches and sugar was often forced upon the attention of the physician in his efforts to properly feed infants, as well as in the management of certain forms of dyspepsia. His own experience tended to confirm the statement expressed by some writers that the Hebrews appeared to be especially prone to glycosuria, and he would attribute this to their indoor life.

The disease, diabetes, is most commonly observed between thirty and sixty years, and more frequently in the male sex. The comparative infrequency of this disorder in early life might be explained by the general activity of the nutritive processes at that period, and the more common occurrence in men by the greater tendency to excessive eating and drinking, as well as greater exposure to traumatism. It could not be denied that sometimes physical strain or mental shock caused the production of diabetes, but he hardly thought that one was warranted in including excessive muscular exertion and paludal poisoning among the predisposing causes. Glycosuria occasionally occurred in persons without apparently affecting their general health, at least for a considerable time. In the mild form, only an ounce or two of sugar was voided in the urine in twenty-four hours, and while this could be made to disappear by an appropriate restriction of the diet, a very slight indiscretion would often cause it to return, and to remain for a considerable time. As a rule, the mild form after awhile passed into the grave variety. The most characteristic symptoms were tissue-wasting and progressively waning strength. The latter was particularly striking, and was hardly equaled by any other disease, except possibly typhoid fever. It should be remembered that in glycosuria there was a failure to evolve more force than was absolutely necessary for the demands of organic life. The other prominent symptoms —the thirst, the diuresis, and the inordinate desire for food—were all indications of the effort made by Nature to eliminate the sugar and repair the damage. There was often more water passed than was ingested during the same period of time, and this readily explained the desiccation of the tissues so characteristic of the disease. Among the more important complications of glycosuria were neuralgias, particularly of the sciatic distribution, parasthesiæ of various kinds, eczemas and other cutaneous manifestations, and albuminuria. It should be the rule when endeavoring to treat a specially obstinate case of neuralgia to examine the urine for sugar. The albuminuria associated with glycosuria is usually slight, although where it alternates with glycosuria, it may be considerable, and the diuresis very copious. This complication was more commonly observed in cases of senile glycosuria, and is probably, in most instances, an indication of the interstitial nephritis found in gouty or lithemic subjects.

As to the prognosis of this complication it might be said that individuals suffering from both albuminuria and glycosuria often enjoyed a very fair degree of health for a long time. It was well known that diabetes was also very frequently associated with obesity. One of the most troublesome complications of glycosuria was the obstinate constipation, which resisted, in many instances, the most powerful purgatives. There was an acute form of glycosuria, in which the patient usually gave a history of traumatism or great mental and physical strain, which rapidly went on to fatal termination. This, he thought, was probable nothing more than an acute exacerbation of an undiscovered mild glycosuria. As a rule, even in severe cases of the so-called "mild form" of glycosuria, the prognosis was good so long as the patient could be kept under con-

trol, and the disorder might not be incompatible with good and useful health for years. It should be remembered, however, that after a time these mild cases usually passed into the grave form. When the glycosuria persists in spite of a rigid anti-diabetic or animal diet, and especially if associated with an excess of urea in the urine, the prognosis was unfavorable.

There are two principles underlying the rational therapeutics of this disease, viz.: (1) The withdrawal of the carbohydrates; and (2) hastening the transformation of the carbohydrates into their ultimate elements. Of the many drugs, especially recommended for meeting the second indication, it should not be forgotten that not one had been successfully used except in connection with the restricted diet. As both iron and alkalies had the power of hastening oxygenation, they were of service in connection with the dietetic management—indeed, this combination of iron and the alkalies was probably the most useful of all that had been recommended. It was a significant fact that this particular method of medicinal treatment appeared to be of the most signal service in those cases of glycosuria occurring in gouty or lithemic subjects. The inhalation of oxygen gas and the use of enforced exercise would seem to be rational measures, but they had not proved successful clinically. Opium was considered by many to be the best drug for controlling glycosuria, and probably, when combined with the alkalies, it constituted the very best therapeutic method, outside of the dietetic treatment. The latter could not be considered at this time in detail; it could only be stated that the principle of the anti-diabetic diet was the conversion of the physiological type of man from an omnivorous to a carnivorous animal, and that at the present time this change could be effected with much less distress and difficulty than might be supposed.

Dr. William H. Thomson, in discussing the foregoing paper, said that notwithstanding the advances made in physiology and physiological chemistry, the disease, diabetes, remained as great a mystery as ever. He had long felt that it was not at all improbable that Claude Bernard had led us off on a wrong scent, for there were many facts that made it difficult to believe that derangement of the liver was the cause of glycosuria. Thus, in cases of sudden hyperemia of the liver, of brown induration, of neoplasm, of cirrhosis of the liver, glycosuria rarely occurred, and yet in these conditions its function was undeniably disordered, in some instances to a very great degree. During the past ten years some exceedingly interesting physiological experiments had been carried on with regard to the relation of the pancreas to the development of glycosuria. These had revealed the fact that if the whole pancreas were extirpated, glycosuria would ensue, but that if only a small portion of this gland were allowed to remain, and even of the small portion left behind were transplanted to another part of the abdomen, there would be no glycosuria. Further investigation had shown that there were certain cells in the pancreas which produced a secretion which, when circulating in the blood, prevented the production of glycosuria. When one recalled in this connection the well known and extensive changes in nutrition which follow the removal of the testicles, and the profound changes occurring in the osseous system consequent on the removal of that insignificant little gland, the pituitary body, it was evident that there was much yet to be learned regarding the exact relations of the glands to the human economy. He thought it quite possible, therefore, that diabetes might have a relation to the genesis of the glycolytic ferment.

Turning to the clinical aspects of glycosuria, Dr. Thomson said that age was a most important element in the prognosis—that younger the patient, the worse the prognosis. In an old person, glycosuria did not seem to shorten life, but, on the contrary, sometimes seemed to be a positive benefit. He did not believe that the glycosuria of old age was the same disease as glycosuria occurring in young subjects, the clinical manifestations were so totally different. If he might be allowed to propound a theory of diabetes, he would say that, as it had been conclusively proved that the starchy elements of the food were burned up in the muscles and not in the liver, and as in diabetes the difficulty was from the loss of the power of burning up the sugar, he thought it quite possible that diabetes might be due to a disturbance in the innervation of the muscles. This theory, at any rate, would satisfactorily explain many of the well-known clinical phenomena of the disease.

Dr. A. H. Smith said that one point seemed to be quite clear, and that was that the starting point of diabetes was a perversion of nervous influence. He had had in his own practise a striking example of the immediate development of diabetes as the result of profound mental shock, in the case of a gentleman who had been in good health until he had been involved in a runaway accident, after which he had promptly become diabetic. He had ascertained from the actuary of the life insurance department of the Brotherhood of Engineers that locomotive engineers were about seven times more liable to diabetes than other classes of men, and from the same source the probable reasons for this had been stated to be: (1) The constant jarring in the engine-cab; (2) the alternate cooling and heating of the body as the engine was in motion or at rest: and (3) the constant and excessive mental strain involved in this occupation. Dr. Smith said that he had came to think that the moment sugar began to circulate in the human organism, it continued to irritate the sensitive centre from which the disease had originated, and that in this way a vicious circle was established. He considered the element of heredity of so much importance, that he believed that a diabetic father should exercise extreme care in the selection of a business for his son, so that the latter would not be subjected to such strain or excitement as would be likely to develop the disease. He could confirm all that had been said by the previous speaker regarding the comparative mildness of glycosuria in old persons, and in this connection he also wished to utter warning against a too rigid enforcement of the anti-diabetic diet which, he believed, sometimes was responsible for precipitating the condition of acetonemia.

Dr. W. G. Thompson said that while indirectly heredity was an important element in the production of dia-

betes, it should be remembered that many people gave evidence of an inability to easily digest starchy foods, and yet they failed to develop glycosuria. When it was once developed it seemed to be under the control of the nervous system, and it was probably on this account that opium had been found such a useful remedy in the treatment of diabetes. So far as his observations had gone, there was but little danger of invoking the opium habit by such treatment. He much preferred opium to codeia, as the latter had been productive of but little benefit in his hands, in the treatment of this disease. He had been much interested in what had just been said regarding the danger of a too strict enforcement of an exclusive diet, and he believed that the best guide was the weight of the patient. This should be taken very frequently, and if there was a steady diminution in weight it was evident that the diet should be more liberal.

THE CUTANEOUS MANIFESTATIONS OF DIABETES.

Dr. Prince A. Morrow presented a paper on this subject in which he said that the skin was especially liable to give evidence of the impaired nutrition consequent on the development of diabetes, and that it was in diabetic subjects very prone to undergo suppuration, inflammation, or gangrene. He would divide the cutaneous manifestations of diabetes into two classes, viz.: (1) Those evidently of diabetic origin; and (2) those occurring occasionally or incidentally in the course of diabetes. In this disease there was often a very noticeable scantiness of the perspiration, and a harshness or fine desquamation of the skin. Pruritus, not only of the genitals, but of the general surface, was one of the most common of the disorders of sensation associated with diabetes. Among the trophic disorders might be mentioned the thinning and falling of the hair, and the falling of the nails. Erythema was observed in situations not reached by the urine, and consequently the idea that it was always due to the irritation of this excretion was not correct. Diabetic eczema of the female genitals was to be distinguished by the marked infiltration, the abundant secretion, and the glazing of the surface; in males it was characterized by the acuteness of the inflammation, the redness of the surface, and the profuse discharge, which in some instances was sero-purulent. Of the diabetic manifestations on the general surface of the integument, furuncles were the most common, and they were characterized by a greater multiplicity and tendency to sloughing than in ordinary boils. *Xanthoma diabeticorum* was a disease peculiar to diabetes, as its name indicated, and disappeared with the cessation of the glycosuria. *Herpes zoster* was sometimes especially severe in diabetics.

Dr. G. H. Fox said that he recalled seeing two cases of *xanthoma diabeticorum*. When an eruption of pale yellowish, flattened nodules was present on the lower portion of the back and buttocks, it might be said that the diagnosis of glycosuria was written on the skin.

Dr. S. Sherwell said that in his opinion a physician would be almost guilty of criminal negligence who would neglect to examine the urine for sugar in a case of extensive and persistent furunculosis, or in a severe case of pruritus vulvæ of obscure origin. In connection with this subject he wished simply to call attention to a papular, pustular, or pemphigoid eruption, named by Duhring herpetiformis, which was now known to be intimately associated with glycosuria.

REVIEWS.

The Toxic Amblyopias: Their Symptoms, Pathology, and Treatment. By George E. De Schweinitz, M.D., Clinical Professor of Ophthalmology, Jefferson Medical College of Philadelphia. Octavo, 240 pages, forty-one engravings, and nine full-page colored plates. Limited edition. De Luxe binding. Lea Brothers & Co., Philadelphia and New York, 1869.

Dr. De Schweinitz has evidently entered upon the study of toxic amblyopias with genuine interest in his subject, and he has not been content simply to familiarize himself with the work of other investigators in this field, but has supplemented their observations by numerous carefully conducted experiments of his own. His study of the literature of the subject, it is evident, has been most exhaustive, and not the least valuable feature of his monograph, are the very full bibliographical references which it contains. Nearly one-half of the volume (104 pages) is devoted to the consideration of alcohol and tobacco amblyopias. He differs from Nettleship, Eales, Gunn, and others, in believing that alcohol alone is capable, as tobacco is, of producing a definite form of amblyopia. The presence of impurities in the spirituous liquors consumed, especially of fusel oil, is thought to be an important factor in the production of amblyopia. Before the thirty-fifth year, amblyopia from alcohol is said to be exceedingly uncommon.

The pathologico-anatomical basis of "intoxication-amblyopia" (alcohol and tobacco-amblyopia) is a sclerosing inflammation, involving only a limited portion of the optic nerve, the papillo-macular bundle, and comparable to the interstitial hepatitis of chronic alcoholism. The clinical expression of this pathological process, is the existence of a central color-scotoma, especially for red and green, which in advanced and neglected cases, may become an absolute scoloma, in which there is not even light perception. Hirschberg believes that a differential diagnosis between tobacco-amblyopia and alcohol-amblyopia can be established by the location and form of this scotoma. In alcohol-amblyopia the scotoma is "peri-central," *i.e.*, it lies about the macula; whereas, in tobacco-amblyopia it is "para-central," being more distinctly oval in shape, and extending from the macula to the blind spot.

The author regards the smoking of strong tobacco as the most common cause of tobacco-amblyopia. He has met with one very interesting case in a young woman in whom amblyopia was produced by working in a tobacco factory, and he refers to other cases of a similar character. He does not believe that nicotin is chiefly responsible for the impairment of vision. The susceptibility to tobacco increases with age. It is also influenced by race—the

Turks and Spaniards enjoying a comparative immunity from tobacco-amblyopia.

The statement on page 86, that "the prognosis of pure tobacco-amblyopia is always good, provided the patient will abstain from tobacco," we regard as too sweeping. The stage at which the case comes under observation is necessarily a most important factor in determining the prognosis. Bichlorid of mercury, iodid of potassium, nitroglycerin and digitalis, in addition to strychin, are the remedies which are especially recommended in intoxication-amblyopia.

The section chiefly devoted to quinin amaurosis is especially full and interesting, and the visual disturbances of chronic lead-poisoning are also treated of at length.

The book is well printed, on heavy paper, and the plates, showing sections of the optic nerve, etc., are excellent. It is bound in white cloth, with gilt lettering, and presents a very attractive appearance, quite unlike the usual medical volume. The proof-reading seems to have been done with considerable care, but a few typographical errors have arrested our attention. At the bottom of page 21, the word "are" has been accidentally omitted; on page 35, "glonoin" is printed "gloniin"; the fraction on page 92, which should tell us the dose of glonoin, is incomplete; an important comma is omitted in the seventh line from the bottom of page 106; "to" must be supplied after "He refers" near the bottom of page 191; "is" is printed "in" in the fifth line from the bottom of page 193, and in the third paragraph from the top of page 207, "fails to avoid objects" instead of "avoids objects" is, we presume, what was intended.

The book is one that the scientific practitioner of medicine, as well as the specialist in ophthalmology, may read with interest and profit, and feel under obligation to its author for placing it within his reach.

OBITUARY.

Dr. J. West Roosevelt, a prominent physician of New York City, died suddenly of pneumonia, at his home in this city, Friday morning, April 10th. He developed his first symptoms on Thursday morning, but the disease advanced with alarming rapidity, edema of the lungs developed, and he died just eighteen hours from the onset of the disease. Death came so suddenly that it was a great shock, not only to his family and immediate friends, but also to the whole profession of the city. Dr. Roosevelt was an active member of the Academy of Medicine, the Medical and Surgical Society, the Pathological Society, and the Practitioners' Society. As a member of the Academy of Medicine, he became an active worker in the investigations undertaken by that organization in exposing the abuses that existed in the Croton watershed, and the exposure of the political corruption in the New York Quarantine Department. He was prominent in the movement that was made for the national control of the entire quarantine system.

Dr. Roosevelt was born in New York, July 2, 1858. He graduated from the Academic Department in Columbia College, and in 1880, received his degree from the College of Physicians and Surgeons. Upon his graduation, he went immediately abroad, where he spent several years in study at the various hospitals, and upon his return to this country, he began the practise of medicine in New York City. Although doing a general practise he made a study more especially of the diseases of the chest, and was considered an authority upon that subject. He was not only a thorough student, but a hard worker in his profession. He was attending physician at Roosevelt and Bellevue Hospitals, and also at the Seton Hospital, in Yonkers.

He was a first cousin of Theodore Roosevelt, president of the New York Police Board, and also of James R. Roosevelt, secretary of the Legation at London. Dr. Roosevelt married Miss Laura D'Oremieulx, who is left with three of five children that were born to them.

Dr. James J. Mapes, a noted physician among the younger members of the profession in New York City, died Friday, April 10th, at Saranac Lake, from tuberculosis after an illness lasting nearly six months. He was a son of Charles V. Mapes, and grandson of Professor J. J. Mapes, a scientist, after whom he was named, and a nephew of Mrs. Mary Mapes Dodge.

Dr. Mapes was graduated from the School of Arts of Columbia College in 1888. He was well known as an athlete during his college course, and was so popular among his fellow students that for three years in succession he was president of his class. His bright mind and powers of application attracted attention during his course in the College of Physicians and Surgeons, and at his graduation he stood at the head of his class. During his course there he spent his summers at the University of Edinburgh, Scotland, where he won the gold medal for the highest honors in anatomy. After his graduation he gained his hospital experience in the New York Hospital, and then went abroad and continued his studies at Vienna and Paris. While in Paris he studied under Dr. Roux at the Pasteur Institute when the discovery of the antitoxin for the cure of diphtheria was made. Upon his return to this country in January, 1895, an epidemic of diphtheria prevailed at the Nursery and Child's Hospital. He was appointed resident physician, and applied the antitoxin treatment with marked success. He contributed two articles on the antitoxin treatment of diphtheria to the *New York Medical Journal*, and delivered a series of lectures on the subject before the New York Polyclinic. Six months ago his health broke down, and he fell a victim to tuberculosis. He went promptly to Saranac Lake, where he remained until his death.

The sacrifice of this young and brilliant life, for Dr. Mapes was not yet thirty, is another example of the fatal tendency in the medical profession to overwork. He was one of five brothers, four of whom were noted athletes during their careers at Columbia College. An over-confidence in his physique undoubtedly prompted him to his excessive labors.

Dr. Mapes was a member of the University Athletic Club, the Psi Upsilon Club, and the Columbia College Alumni.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXVIII. NEW YORK, SATURDAY, APRIL 25, 1896. No. 17.

ORIGINAL ARTICLES.

THE SURGICAL TREATMENT OF ROUND ULCER OF THE STOMACH AND ITS SEQUELÆ, WITH AN ACCOUNT OF A CASE SUCCESSFULLY TREATED BY LAPAROTOMY.

BY R. F. WEIR, M.D.,
OF NEW YORK;
SURGEON TO THE NEW YORK HOSPITAL, ETC.,
AND
E. M. FOOTE, M.D.,
OF NEW YORK;
SURGEON TO THE RANDALL'S ISLAND HOSPITALS.

THE operative treatment of round ulcer of the stomach and its sequelæ is a subject which has received much attention at the hands of surgeons in the past few years; and before relating the case, which was the incentive to this paper, it will be profitable to see what has been gained by surgical measures, and what is further to be hoped for along such lines.

The statement may to many seem a strange one, but gastric ulcer is one of the commonest diseases. The number of persons in Europe affected with it has been estimated[1] to be between 4 and 5 per cent. of the whole population, although no two writers agree on the exact figures, which range from 1.23 to 13 per cent., and Fiedler,[2] who examined, *post-mortem*, 2200 stomachs, found ulceration or its scar in 20 per cent. of the women, and 1.5 per cent. of the men. The disease occurs most commonly, as is well known, in early adult life (twenty to forty years), though the greatest mortality occurs at a later age (forty to sixty years).

Naturally it is of vital interest to the surgeon to know in what part of the stomach an ulcer is likely to be situated. It used to be stated that most ulcers occurred in the posterior wall and lesser curvature. Thus Brinton, who wrote his book on "Diseases of the Stomach," in 1858, said that 70 per cent. of gastric ulcers occupied these two situations. This view is not sustained by some recent investigations. Ewald says that ulcers occur especially in the greater curvature and in the pyloric region; or that part of the stomach which sustains the impact of irritating food, and also in that part which hangs lowest in an upright position[1], and in which the contents therefore collect. Ewald supports Nolte's figures that the relative frequency is as follows: in the greater curvature, 54 per cent.; in the pyloric region, 32 per cent.; in the anterior wall, 7 per cent.; in the posterior wall, 5 per cent., and in the cardiac region, 2 per cent.

Though usually the ulcer is single, two or more may be present, a circumstance which may affect the result of an otherwise successful operation. Orth[2] says that in twenty per cent. of the patients who suffer with gastric ulcer, more than one ulcer is present. As many as five have been found. This has an important bearing to be hereafter mentioned in the surgical treatment of non-perforating ulcers, *i.e.*, for the relief of pain or hemorrhage.

Even though so frequently met with, as has just been shown, the large majority of cases of gastric ulcer are successfully treated by rest in bed, appropriate diet—with perhaps rectal feeding for a time—and sedatives and laxatives, followed by tonics. But in certain cases these measures fail to relieve the severe symptoms; in others complications arise, notably perforation and hemorrhage, and in some instances intractable gastralgia, which all our therapeutic measures may be powerless to meet; in still others, by mechanical action the ulcer or its scar obstructs the pylorus, or establishes adhesions between the stomach and some adjacent structures, and thus interferes with the function of the viscus to a serious or to a painful degree.

The question of operative relief is pertinent then to such cases. It is most imperative in the perforation of an ulcer, and that subject will therefore first be discussed.

PERFORATION.

Perforation of a round, *i.e.*, non-malignant, gastric ulcer, is a serious complication, which, according to Comte,[3] occurs in about fourteen

per cent. of the cases of that disease, and when it has taken place, it is nearly always fatal. Barling[1] says that ninety-five per cent. of the patients having such perforations, unless operated upon, die; and among the five per cent. of reported recoveries are some in which decided doubt may be cast upon the diagnosis, which is not always an easy one to establish.

When perforation does take place, one of three conditions obtains: (1) If adhesions are scanty, the stomach contents escape into the general peritoneal cavity, and a general peritonitis results. Such is apt to be the case in anterior perforations where adhesions are the exception, on account of the mobility of the anterior stomach wall, or of the adjacent hollow or solid viscera. (2) Adhesions may form, and the abdominal contents escape slowly. In these cases there is a localized peritonitis which may advance to an abscess, or the barriers of lymph may yield, especially if on the anterior wall, and a general peritonitis follow, as often happens in appendicitis. If the perforation presents itself posteriorly, the lesser peritoneum may become involved, and a large food of abscess result—*subphrenic abscess*. Very rarely it has happened that an adherent perforation has produced an abscess in the liver, without other lesion. Abscesses in the spleen are more frequent. (3) Adhesion of the stomach and discharge of its contents into a hollow organ. This is a very infrequent complication, which needs only to be mentioned.

PERFORATION INTO THE GENERAL PERITONEAL CAVITY.

This condition is indeed desperate, but under fortunate circumstances the *vis medicatrix naturæ* has been equal to the repair of even this lesion, and some dozen cases are on record, in which recovery has been perfect, though an undoubted perforation had occurred. In some of these cases evidences of the healed perforations have been found at a subsequent autopsy.

Pariser[2] has collected fourteen well-authenticated cases of acute gastric perforation, followed by recovery, without operation. In most of these it was distinctly stated that no food had been taken for some hours (three hours to three days), and the recovery in all such cases, according to this writer, depends upon the empty condition of the stomach. He is able to add a fifteenth case, which occurred in his own practise:

The patient, a woman, aged thirty-one years, had been under treatment for years for gastric ulcer, of which she presented all the clinical symptoms, including vomiting of blood. The various plans of treatment, including that recommended by Fleiner, of large doses of bismuth, were successively tried, without avail. Then starvation was resorted to. For three days nothing but an occasional spoonful of cold, boiled water passed her lips. On the third day all pain had subsided. On the evening of that day, after a quick movement of the body, there was sudden pain over the cardiac end of the stomach and collapse, with sunken eyes, imperceptible pulse, etc. In the weak condition of the patient, and the ill-adapted surroundings, Pariser concluded that an operation would be fatal, and he hoped to avoid peritonitis because of the empty stomach. For eight days rectal nourishment was adhered to, and after well-marked signs of localized peritonitis, the patient recovered.

But rest and rectal feeding offer so slender a hope of recovery that without the help of surgery it would still be true, as Leube once said, that "when perforation occurs—that most disastrous event in the course of gastric ulcer—the only treatment in most cases is to induce euthanasia."

It is, however, only in the last few years that surgical relief has been thought of as applicable to perforation of the stomach. In 1883 Nelson C. Dobson[1] lost a patient from gastric perforation. At the autopsy, the opening was found to be in the anterior wall, and so accessible that he reported the facts, and advocated in a similar case operative interference along one of the following lines: (1) Simple abdominal section with cleansing of the peritoneum, leaving the ulcer to heal of itself under rest and rectal feeding. (2) The closure of the perforation by suture either with or without paring its edges. (3) The suture of the stomach, at the point of perforation; to the abdominal wall in order to establish a gastric fistula.

These are principles which have been common to other minds. In 1880 Mikulicz sewed up an opening in the lesser curvature of the stomach of a man whose history was unobtainable. From the appearances at the operation as well as at the autopsy, it seemed likely that the perforation was not due to a recent ulcer, but to traumatism, the organ giving way at the site of a cicatrized ulcer. In 1885 and in 1887, Czerny did an unsuccessful case of suture of a perforated ulcer. Van Wahl in 1889, and Mouisset, 1890, published each a fatal case. These cases, together with one reported by Weir, likewise fatal, were published in the *International Medical Magazine* for February, 1892. It is not yet four years since the first suc-

cessful case was published by Kriege,[1] so that every contribution is of interest, which will add to the knowledge of a subject whose diagnosis and treatment are still imperfectly understood. Since that time the surgical treatment of perforating gastric ulcer of the stomach has widely spread, particularly in Great Britain, so that now the collection of such operations has attained a total from careful personal research of seventy-seven cases, obtained from American, English, German and French periodicals up to date.[2] Included in the report is a detailed account of a successful result by operation in a case under our joint charge where the happy issue was largely due to the two factors of a positive diagnosis and a promptly following laparatomy.

PERFORATING ULCER OF STOMACH—EARLY LAPAROTOMY RECOVERY.[3]

Mary B., consulted me in August, 1894, for an obstinate cough, with scanty expectoration and pain in the sternal and right scapular regions, with dyspnea on exertion, headache, anorexia, and constipation. She had twice spit up a small amount of blood. For four months she had had night sweats. The patient was at that time fifteen years old, heavy but anemic. Physical examination showed dulness and fine moist râles at the left apex, and right base behind, and she had an afternoon fever. Under tonic and expectorant remedies, and a month's residence in the mountains of Sullivan County, N. Y., she gained weight and the râles disappeared, except at the base of the right lung. The following winter she neglected herself, and, when I next saw her in April, 1895, her cough was worse, and she had moist râles over the greater part of both lungs, and she had lost six pounds in weight. Though living in poverty, she was able, through friends, to spend three months of the summer in the mountains, and she did not return to the city until the last of September, 1895, when she took a position as maid in an apartment, where the work was light and her food good. Her health was excellent, the cough and râles had disappeared, and her weight, 110½ pounds, was greater than it had ever before been. I was never able to get any sputum for examination, but the signs of pulmonary tuberculosis had been too well marked to be doubted.

She had frequently been troubled with indigestion, and at various times had vomited her food, but these symptoms had not been the prominent ones. About November 20, 1895, she began to have severe gastric pain, and her appetite failed her. She spoke to no one about it and kept on with her work, though eating almost nothing. The pain, too, was at times so severe that she was compelled to lie down. November 27th, at 10 A.M., she was attacked with a colicky pain in the gastric region so severe that she rolled upon the floor in agony, and vomited a small amount of coffee, which was the only nourishment she had taken that day. About noon she felt a little relief, and went home by the elevated road. To do this, she walked about a quarter of a mile, and climbed up and down some fifty steps. Late in the afternoon she sent word to me that she had an "attack of pain in the heart." At 6.30 P.M., I found her lying on her back, quiet and without much pain. Pulse, 120; temperature, 102°. The facies, though not well marked, was of a purely abdominal type. The chest revealed nothing abnormal. The abdomen was somewhat rigid, and more so on the left side than on the right. There was moderate tenderness on pressure in the epigastric and left iliac regions. There was no distention, nor tympanites. Respiration was almost wholly thoracic. Palpation revealed nothing but the seat of tenderness. The pain was described as commencing to the left of the median line under the costal border, and extending thence to the left groin and into the left thigh. Appendicitis was out of the question, and the symptoms did not seem those of any form of intestinal obstruction. The diagnosis of perforated gastric ulcer was made, and an immediate operation advised. Dr. Weir kindly consented to admit the patient to his service at the New York Hospital, where he performed laparotomy, and sutured the stomach at 9.30 P.M., a little over eleven hours after the onset of the attack.

Under chloroform, a median incision 4½ inches long, was made above the umbilicus. An unusual amount of subperitoneal fat obscured the peritoneum. When its cavity was opened the stomach presented in the wound. The greater curvature appeared normal. There was no general peritonitis. The anterior surface of the stomach was adherent to the liver by recent lymph. As it was separated, a hissing sound was heard, due to the escape of gas from the stomach through the perforation.

The opening was found without difficulty. It was minute—not one-fourth inch in diameter, with necrotic edges, and lying in the centre of a dense ring of inflammatory and fibrinous tissue, which involved the whole thickness of the wall of the stomach. This thickened area was about two inches long and one inch wide, and was situated in the anterior wall of the stomach, about midway between the greater and lesser curvatures, and perhaps one-third of the distance from the pyloric to the cardiac orifice.

In separating the stomach from the liver, some

[1] Heusner, *Berl. klin. Wochenschr.*, 1892, p. 1280.

[2] Comte, in the article already referred to, says that he has collected sixty-five cases of laparotomy for perforation of a gastric ulcer with forty-six deaths. He gives no details nor references whence they were obtained. He may have, and probably has, included, to make up the total, perforations associated with chronic subphrenic abscess. As the clinical picture and treatment of these two sets of cases are so distinct, it has been thought better in this paper to keep them separate. Those cases have also been excluded where no data have been given excepting the name of the operator.

[3] Reported by Dr. Foote.

thin, greenish fluid, containing a few flakes of curdled milk, escaped. This was sponged away as quickly as possible, while the perforation was promptly closed by the finger's end until gauze pads could be placed in position around the field of operation.

Two silk stitches were first inserted through the wall of the stomach, across the perforation, to stop the escape of gastric contents, and then the perforation was carefully closed in layers—Lembert style—with fine black silk. The fold in the stomach was made transverse, which was also the direction of the long diameter of the thickened area spoken of above. Owing to the hyperplastic condition of the wall of the stomach about the perforation, some of the peritoneal stitches of the first row cut the tissue and could not be drawn tight. The second row held better, and when a few additional stitches were applied in the centre as a third row, the closure was complete. About twelve peritoneal sutures were used in all. No collections of stomach contents were anywhere found, and a sponge thrust into Douglas' pouch and into the upper peritoneal cavity, came back clean. A stomach tube was then introduced through the mouth, and the stomach carefully washed out. The contents consisted of a sour, bile-stained fluid, containing a small amount of coagulated milk and three or four bits of orange. By this lavage the stomach was moderately distended, but no drop of fluid leaked through the suture. Abdominal irrigation was not employed, but the peritoneum was wiped with moist gauze wherever the gastric contents had soiled it. The abdominal wall was closed in three layers, *i.e.*, peritoneum, fascia, and skin, with catgut, kangaroo tendon, and black silk, respectively.

The operation lasted about one hour, and the patient left the table in only fair condition, with a pulse of 150. For two days there was frequent and very distressing vomiting, temporarily relieved by gentle lavage with diluted Thiersch's solution. After the second day the vomiting subsided, and water was allowed by the mouth. Fluid nourishment was given on the third day, and the nutrient and stimulant enemata, which had been given every six hours following the operation, were stopped in four days. There were at no time any signs of general peritonitis. Recovery was otherwise uneventful.

As an offset to this case, a second one is presented with a fatal issue, where the diagnosis was obscure and the interval between the attack and the operation unduly prolonged. Chronologically, this preceded the one just given, and contributed much in the way of instruction. The patient was treated for two days by an outside physician, and then sent to the New York Hospital and placed in Dr. Weir's charge January 19, 1895. The following is an abstract from the hospital records:

P. K., forty-four, male. Gastric history of one year's duration, with indigestion growing steadily worse. On two occasions there have been crises marked by an attack of severe pain, and followed by vomiting; but no hematemesis has ever occurred.

Two days ago, following a drinking bout, there was an attack of sharp epigastric pain, so severe that it required two grains of morphin, administered hypodermically, to relieve it. The pain rapidly spread and later was more intense in the right iliac region. Vomiting followed the attack and has persisted. The abdomen was at first retracted. On the day following the attack, hiccough began and has continued.

On entrance to the hospital, forty-eight hours after the attack, the face was drawn and anxious, and the pulse weak and rapid (P. 140, R. 36, T. 104°), abdomen not distended, but intensely tender and rigid, especially in the region of the appendix. Extremities cold.

Immediate operation was determined upon and performed by Dr. Weir, chloroform being administered. A four-inch incision was made over the appendix, and that organ being somewhat enlarged, was excised. It contained no perforation, was not adherent, and evidently was not the origin of the general purulo-fibrinous peritonitis which was present. The pelvis was found to contain over a pint of bloody, purulent fluid.

A four-inch median incision was then made above the umbilicus, and a perforation was discovered in the anterior wall of the stomach about one-fourth inch in diameter. It was situated about one inch from the pylorus. Pressure on the stomach caused the escape, through the perforation, of air and some bilious matter. No adhesions were present to shut off this opening. It was closed with two rows of silk sutures—Lembert style. The abdominal cavity was sponged as clean as possible, and drained through both wounds with iodoform gauze. Stimulant and nutrient enemeta were given, and other stimulants were administered hypodermically, but the patient survived only ten hours. Examination of the appendix showed that the inflammation was for the most part confined to its peritoneal coat.

REMARKS.

An examination of the tables here presented reveals several interesting facts.

Sex.—Five-sixths of the seventy-eight cases of gastric perforation occurred in women—eighty-two per cent. Brinton found that two-thirds of his 234 cases of perforation occurred in women, the perforation being the same as that of gastric ulcer, without perforation.

In perforation of duodenal ulcers (Table II) the figures are reversed, eight cases being males and only one a female. Latham[1] reports twelve autopsies, performed upon patients who had died

TABLE I.—LAPAROTOMY FOR ACUTE PERFORATION OF GASTRIC ULCER.

No.	Sex.	Age.	Previous History.	Character of Attack.	No. of hours before Operation.	Condition at Operation.	Site of Perforation.	Operation.	Result.	Operator and Reference.
1	M	28	Gastritis	.....	Several.	Abdomen distended, tender.	Lesser curvature near cardiac end. Alcoholic fluid in cavity.	Perforation sutured Irrigation 1–1000 thymol.	Death in 3 hours. Probably traumatic rupture in an old healed ulcer.	Mikulicz, *Volk. klin. Samm-lung. Chirurg.*, 1885, p. 2310.
2	F	20	Gastritis 3 mos.; no vomiting.	.....	72	Prostration. P. 120, R. 60.	Ant. surface 3 in. from cardiac end (autopsy).	Ulcer not found. Fibrinous peritonitis; drainage.	Death in 4 days.	Czerny, reported by Steinthal, *Archiv f. klin. Chir.*, 1888, v. 37, p. 853.
3	M	33	Indigestion 8 yrs.; no blood.	After dinner sudden epigastric pain.	50	R. 36, P. 152.	Ant. surface near pylorus.	Ulcer closed by two rows of stitches. Irrigation .6 per cent. salt sol.	Death in 9 hours.	*Ibid.*
4	M	24	Gastric history.	.....	.....	Abdomen distended. Liver dulness diminished.	Lesser curvature (autopsy).	Purulo-fibrinous peritonitis; liver and stomach adherent; adhesions not disturbed. Irrigation, drainage.	Death the same day. Perforation found to be behind the adhesions, between liver and stomach.	Köhler, *Charité Annal*, vol. 15, 1888–9, p. 450.
5	F	47	Gastric history of 10 years; gastric ulcer.	During defecation, sudden abdominal pain.	18	Abdomen distended. Liver dulness decreased. Collapse.	Lesser curvature.	General peritonitis.	Death on the table.	*Ibid.*
6	F	16	Gastric ulcer.	Violent pain left side of abdomen. Later, vomiting.	24	.....	Stomach not examined. General peritonitis.	Irrigation and drainage.	Death 2 mos. later from empyema and abscess of lung. Autopsy showed ant. perforation.	Taylor, *Birming. Med. Rev.*, 1888, vol. 23.
7	F	17	Six mos. indigestion, vomiting, no blood.	Pain lower abdomen, caused unconsciousness.	34	.....	Anterior surface near pylorus; fibrino-purulent peritonitis.	Ulcer sutured; irrigation, boracic solution; drainage.	Death in 24 hours.	Czerny, *Arch. f. klin. Chir.*, 1889, vol. 39, p. 780.
8	F	Young	Gastric ulcer.	Sudden pain.	18	.....	Fibrinous peritonitis.	Ulcer sutured.	Death in 10 days. Subphrenic abscess had broken into l. pleural cavity. Suture in stomach firm.	Stelzner, *Verhand. d. Deutsch. Ges. f. Chir.*, 1889, p. 98.
9	F	Young	Gastric ulcer.	Sudden attack.	48	.....	.....	Ulcer sutured.	Death in 4 days from purulent peritonitis, following an unobserved second ulcer. Suture firm.	*Ibid.*
10	F	17	Gastric ulcer, no hematemesis.	Sudden pain lower abdomen.	34 (about)	Distended abdomen. Tenderness, especially in epigastrium. P. 120.	Anterior wall between curvatures, near pylorus.	Purulo-fibrinous peritonitis; perforation closed by 3 stitches; irrigation; drainage; op. 1½ hours.	Death in 24 hours; a second ulcer extended into the substance of the pancreas.	Mikulicz, *Arch. f. klin. Chir.*, 1889, vol. 39, p. 780.
11	M	46	Two years gastric ulcer, vomiting no blood.	Increased pain and vomiting.	120	Liver dulness diminished. Dulness l. lumbar region shifting with changed position.	Ant. surface near lesser curvature (autopsy). Much serous fluid.	Ulcer not found.	Death in 33 days from general peritonitis.	v. Wahl. Reported by Nissen, St. Petersburg *Medical Wochenschr.*, 1890. Nos. 41–42.

No.	Sex.	Age.	Previous History.	Character of Attack.	No. of hours before Operation.	Condition at Operation.	Site of Perforation.	Operation.	Result.	Operator and Reference.
12	M	34	Daily vomiting—never of blood.	Sudden epigastric pain after morning coffee, no vomiting.	30	Peritonitis.	Anterior surface near lesser curvature.	Stitches would not hold in necrotic wall.	Death at end of operation.	Mouisset, *Lyon Médical*, 1890, p. 516.
13	F	21	.....	Sudden violent abdominal pain and vomiting.	60	.....	Anterior surface. (Autopsy). General peritonitis.	Ulcer not found; drainage.	Death in 8 hours.	Parsons, Dublin *Jour. Med. Sci.*, 1892, p. 27.
14	F	.....	Indigestion.	Violent pain l. hypochondrium. Collapse.	8	.....	Anterior surface, close to lesser curvature, cardiac end.	Ulcer could not be sutured. Stomach stitched to abdominal wound.	Death in 6 days.	*Ibid.*
15	M	41	Gastric ulcer.	Severe epigastric pain. Collapse.	8	.....	Anterior surface, cardiac end.	Both recti cut transversely, ulcer sutured, no irrigation. Drainage.	Recovery. No nourishment by mouth for 13 days.	Kriege. Reported by Heusner. Berlin *klin. Wochen.* 1892, p. 1280.
16	F	21	Four we'ks hematemesis and pain.	Sudden abdominal pain. Treated by morphin for two days.	57	Peritonitic signs, well marked.	Anterior surface, near cardiac orifice. Gastric contents in vicinity. A pint of pus in the pelvis.	L. rectus cut transversely. Ulcer sutured. Sponging. No irrigation. Operation 1^{1}_{2} hrs.	Death in 10 days from peritonitis, following a duodenal perforation, due to intestinal obstruction. The small intestine was caught in a rent in the omentum. Suture in stomach gangrenous.	*Ibid.*
17	F	71	40 years ventral hernia.	Following strain, sudden abdominal pain and vomiting.	48 (about).	Dulness and resistence right hypochondrium.	Posterior wall. (Autopsy).	Incision over tumor. General peritonitis. 81 stones removed from gall-bladder. Cystic incision sutured. Drainage.	Death next day, gall-bladder not perforated. Peritonitis from perforation of post. gastric wall.	Körte, *Verh. d. Deutsch. Ges. f. Chir.*, 1892.
18	F	Young.	Gastric ulcer.	Sudden attack of pain.	36	Abdomen distended.	Anterior wall, near lesser curvature and cardiac extrem.	Ulcer pared and sutured. Irrigation and drainage.	Death in 5 days from septic peritonitis hastened by hemorrhage from a duodenal ulcer.	Lücke, Pinner, *Centralbl. f. Chir.*, 1893, No. 28.
19	F	18	Imperfect gastric history.	Sudden umbilical pain, vomiting, prostration.	80	Distended peritonitic abdomen. P. 148, T. 100°.	Middle posterior wall, near lesser curvature. (Autopsy).	Stomach not examined. Both tubes and ovaries removed.	Death in 24 hours.	F. Markoe, Weir in *Internat. Med. Mag.* February, 1892.
20	F	57	Gastric history. No vomiting.	Sudden abdominal pain, prostration. Bilious vomiting.	100 (about).	P. 100, T. 100°. Advanced peritonitis.	Middle anterior wall, near lesser curvature. General fibrinous peritonitis.	Ulcer closed by two rows of stitches. Irrigation with Theirsch's sol.	Death in a few hrs.	Weir, *Internat. Med. Mag.* February, 1892.
21	F	22	Indigestion.	Severe abdominal pain. No vomiting.	26	Abdomen distended.	Anterior wall, midway between orifices.	Purse string suture, as Lembert's stitches failed to hold.	Death in 6 hours.	Sterling, *Austral. Med. Gaz.* 1893, p. 281.
22	F	20	Indigestion.	Sudden intense abdominal pain and collapse	9	.....	Cardiac end, rather on the posterior surface.	Ulcer sutured. Irrigation with creolin water. Drainage. The suture in the stomach did not hold, and on the 17th day an unsuccessful attempt at resuture was made. Four days later the stomach was successfully sutured.	Death on the 31st day after first operation from septicemia. There was a large abscess between the stomach and liver.	Gilford, *Brit. Med. Jour.*, 1893, i, p. 944.

No.	Sex.	Age.	Previous History.	Character of Attack.	No. of hours before Operation.	Condition at Operation.	Site of Perforation.	Operation.	Result.	Operator and Reference.
23	F	26	Gastric ulcer, no hematemesis.	Sudden pain, vomiting, and collapse.	14	.....	Cardiac end, posterior wall.	Ulcer could not be excised nor sutured. Stomach stitched to abdominal wound.	Death in six weeks from abscess of left lung and empyema.	Haward, *Brit. Med. Jour.*, 1893, i, p. 952.

Anterior wall, near cardiac end, and 1½ in. from greater curvature.	Lembert's suture, 2 rows. Irrigation with boiled water. No drainage.	Recovery. Nothing by mouth for four days. Left crural phlebitis. Stitch abscess.	Pollard, *Brit. Med. Journal*, 1895, ii, p. 14.
72	F	17	Indigestion. Vomiting.	Sudden pain epigastrium and l. hypochondrium.	11½	Abdomen sl. rigid. Epigastric respiration.	Anterior wall, at about its centre.	Lembert's suture, 2 rows. Lavage per oram. No irrigation nor drainage.	Recovery. Rectal feeding 7 days. Stitch abscess. Well 5 mos. later.	Weir, November 27, 1895. Unrecorded.
73	F	25	2 months gastric pain and vomiting.	Epigastric pain some days.	(?)	Epigastric tumor. T. 101° F.	.....	Stomach adherent to abdominal wall. Perforation not seen. Drainage. No Irrigation.	Gastric fistula which closed spontaneously in about 2 months.	C. P. Parker, 1895. Unrecorded.
74	F	30	Slight gastric symptoms. No vomiting.	Obstipation 4 days.	36	Tympanites. P. 130, T. 97.	Lesser curvature.	General suppurative peritonitis. Perforation admits 2 fingers. Gastrostomy. Irrigation with boiled water. Drainage.	Death in 15 hours.	McCosh, 1890. Unrecorded.
75	M	40	Gastric ulcer.	Severe epigastric pain. No vomiting.	24	Moderate tympanites.	Middle of lesser curvature. (Autopsy).	Purulo-fibrinous peritonitis. Patient could not stand a search for perforation. Drainage.	Death in 14 hours.	*Ibid.*
76	F	49	.....	Sudden abdominal pain and vomiting.	.....	Tympanites. Collapse.	Anterior wall near lesser curvature. (Autopsy).	Gas, fluid, and coagulated milk in the peritoneal cavity. Abundant lavage.	Death in 2 hours.	Sourdille, *Bull. d.l.Soc. Anat.*, 1895, p. 301.
77	F	24	Gastric history. No vomiting.	Sudden severe epigastric pain.	84	Tympanites. Liver dulness absent. P. 120, T. 101.5°.	Anterior wall near superior border.	Gas escaped and stomach presented in wound. The perforation was the size of a 5-cent piece. It was trimmed and sewed. Abdomen sponged. No irrigation. Drainage through incision and in l. flank.	No food by mouth for three days. Recovery.	Kirkpatrick. *Mont. Medical Journal*, 1895, vol. 23, p. 670.
78	F	20	Gastric history. 6 months.	Sudden severe epigastric pain.	18	Tympanites. Collapse.	Anterior wall.	Thick lymph about perforation peeled from stomach wall. Perforation closed in rows. No irrigation. A second incision for drainage below the umbilicus.	Recovery. The lower drainage tube discharged twenty-two ounces before its removal.	Armstrong, *Mont. Medical Journal*, 1896, vol. 24, p. 505.

TABLE NO. II.—LAPAROTOMY FOR ACUTE PERFORATION OF DUODENAL ULCER.

No.	Sex.	Age.	Previous History.	Character of Attack.	No. of hours before Operation.	Condition at Operation.	Site of Perforation.	Operation.	Result.	Operator and Reference.
1	M	35	.....	Sudden pain after drinking bout.	20	Abdomen hard and tympanitic. Absence of liver dulness.	Ulcer perforating into peritoneal cavity 1¼ in. below pylorus. Second ulcer 1 in. below that. (Autopsy).	Incision for appendicitis. Free fluid smelling of sarsaparilla. Appendix and gall-bladder normal. Irrigation with salt solution.	Death in 24 hours.	Stimson. Unrecorded.
2	M	28	.....	Sudden pain in epigastrium and vomiting, following drinking bout.	60	Tympanites. Tenderness right hypochondrium. Prostration. T. 103°.	Posterior wall. (Autopsy).	Incision for appendicitis. No free fluid. Commencing peritonitis. Appendix excised.	Death in two days from general suppurative peritonitis. Autopsy showed the ulcer to be of the posterior wall. Pus had collected between the duodenum and pancreas, and had made its way through the necrotic wall into the jejunum.	*Ibid.*
3	M	28	No previous trouble.	Sudden abdominal pain. Prostration.	13	Distended abdomen. Pain to right of umbilicus. T. 100.6°.	Anterior wall, 1 in. below pylorus.	Ulcer pared and sutured and covered by omentum. Irrigation. Drainage.	Death in 3 hours.	Eve, *Lancet*, 1894, ii, p. 1091.
4	M	28	No previous trouble.	Sudden abdominal pain. Constipation. Vomiting.	6 Days.	Tympanites. P. 104. T. 99.8°.	Upper wall of duodenum, near pylorus. (Autopsy).	Incision below umbilicus. Two pints of pus in pelvis. Perforation not found.	Death in 52 hours from purulent peritonitis.	Lockwood, *Lancet*, 1894, ii, 968.
5	M	61	Gastric ulcer.	Sudden pain right hypochondrium. Collapse.	5	.....	Anterior wall, ¾ in. below pylorus.	Suture. Irrigation. Drainage.	Death in 60 hours from septic peritonitis. Vomited about a pint of blood. Ulcer finally closed.	*Ibid.*
6	M	28	No gastric history.	Pain to left of umbilicus, followed by constipation and on 3d day stercoraceous vomiting.	80 (about).	No fever. P. 130. Great tympanites.	Anterior wall of duodenum. (Autopsy).	Perforation not found. Purulent peritonitis. Drainage.	Death in 7 hours.	Lockwood, "Med. Soc. Trans.," 1892, p. 92.
7	M	41	Indigestion.	Sudden pain, constipation. Vomiting becoming stercoraceous.	(?)	Tympanites.	Posterior wall, 1 in. below pylorus. (Autopsy).	Perforation not found. Diffuse fibrino-purulent peritonitis. Irrigation.	Death in 10 hours.	*Ibid.*
8	F	27	Indigestion.	Sudden epigastric pain. vomiting.	30 (about).	T. 100.6°. P. 120.	Anterior wall, ¾ in. below pylorus.	Ulcer excised. Suture. Irrigation with boracic acid solution. No drain.	Nothing by mouth for 17 days. Apparent recovery. 2 months later intestinal obstruction from adhesions, and death. Duodenum healed.	Dean, "Med. Soc. Trans.," 1894, p. 305.
9	M	.....	.....	Sudden pain in epigastrium. Faintness and nausea.	.....	Tympanites. Liver dulness absent.	Anterior wall of first portion.	Gas and fluid in abdomen. Perforation sutured. Irrigation boiled water. Drainage.	Progressed well for 10 days, then pain and fever continuing till 25th day when abdomen was opened and adhesions and a drop of pus found between liver and diaphr'gm. Wound discharged for some days. Recovery complete.	Dunn, *British Medical Jour.*, 1896, i, 846.

from perforation of the duodenum, and ten of them were in males. Kelynack[1] reported six similar autopsies, all in males.

Age.—The average age of the women in our tables is twenty-five, and three-fourths of them were not above this age. The youngest one was fourteen years of age.[2] The average age of the men is thirty-nine years, and three-fourths of them were over forty years. In Brinton's list, the average age of the women was twenty-seven, of the men, forty-two years.

The average age in the duodenal perforations is essentially the same, viz.: women, twenty-seven; men, thirty-seven years.

Site of the Ulcer.—For convenience of description, the stomach is divided into an anterior and a posterior wall, a greater and a lesser curvature, and into a pyloric and a cardiac extremity. These terms represent areas without definite boundaries, and it is often difficult at operation to locate the exact site of the lesion; but of the cases in Table I, the perforation is said to have been forty-three times in the anterior wall, eleven times in the posterior wall, and six times in the lesser curvature. In twenty-seven cases, the perforation was said to be near the cardiac orifice, and only nine times near the pylorus. These figures do not agree altogether with the results of autopsies. Brinton found perforation to be twice as common in the pyloric region as in the cardiac one. According to Struve, in forty-two autopsies the perforation occurred twenty-one times in the anterior wall, thirteen times in the lesser curvature, and twice in the posterior wall.[3]

It is probable that the difficulty of reaching the cardiac extremity of the stomach through a median incision has sometimes impressed the operator with the idea that the ulcer was situated higher up than was actually the case.

However, the most important point in this connection is simply the accessibility of the perforation, and when we look over the tables with that idea in mind, we find that in the large majority of cases, it could be reached and sutured. In only eight cases is it stated that a suture of the perforation was impossible, either from its location, or the condition of the stomach wall, or that of the patient. This is by no means a bad record, on the contrary, it is an encouraging one.

In sixteen cases, the perforation was not found. In two of these it was considered unwise to separate adhesions between stomach and liver, to look for it—a fatal caution. In several other cases the real cause of the peritonitis was not suspected, and in nearly every case, as the autopsies showed, the lesion was readily accessible to discovery and suture, had a reasonably diligent search been made. In justice, be it said, however, that many of these cases occurred in the earlier days of this still new operation, and the operators had not the experience of others as their guide; also that the serious condition of the patient, often limited the duration of a proper exploration.

Previous History.—In less than one-half of the cases (37 per cent.) is it mentioned that gastric ulcer was suspected before perforation occurred. A few (8 per cent.) gave no previous gastric history, but the largest number (55 per cent.) complained of symptoms, variously interpreted as gastritis and indigestion, in other words, in ninety-two per cent. of the cases the history gave a clue to the diagnosis.

Vomiting.—It has been said that the absence of vomiting is a symptom of gastric perforation, but it does not appear to be so. Struve says that vomiting occurs in two-thirds of the cases, and is only likely to be absent in large perforations. In our own collection, where some history of the attack is given (50 in number), we find that in eighteen (36 per cent.), vomiting was present, while in only four (8 per cent.), is it stated that it was absent. In the remaining twenty-nine (56 per cent.), no reference is made to vomiting, but it would be manifestly unfair to conclude that in all these cases vomiting was wanting. Certainly, the presence of vomiting in nowise argues against the diagnosis of perforation of the stomach.

Elapsed Time.—Another, and the most interesting point, in connection with the surgical treatment of a gastric ulcer, is the time which elapsed between the perforation, and the operation done for its relief. It seems an invariable rule, that perforation is attended with an attack of sharp abdominal pain, so that the time of perforation can usually be determined. We find the average time which elapsed then, to be 36 hours, but the extremes being 2 hours and 336 hours, are so far apart that the average has little value. It is more instructive to notice that in twenty-one cases which recovered the elapsed time averaged nineteen hours, while in two-thirds of these cases it was less than twelve hours. In the fifty-five unsuccessful cases the elapsed time averaged forty-three hours, and over twenty-four hours in two-thirds of

[1] Kelynack, *Brit. Med. Jour.*, 1894, ii, p. 914.

[2] Colgan, Medical News, October 8, 1892, reported a case of a child of $2\frac{1}{2}$ years; attacked with convulsions; T. 106°, P. 150, and death in thirteen hours. No gastric symptoms, but autopsy showed a perforation of the posterior wall of the stomach at the cardiac end and near the greater curvature.

[3] Weir, *Internat. Med. Mag.*, February, 1892.

these cases. It requires, therefore, no discussion to prove how much better is the chance for recovery, when a perforation has existed ten hours than when it has existed twenty hours or more, and when a more certain diagnosis brings the patient sooner to the operating table, the percentage of recovery which, in the cases recorded up to date, is about twenty-nine per cent., will doubtless be improved.

Elapsed Time.	Recovery.	Death.	Mortality.
Under 12 hours...	14	9	39 per cent.
12 to 24 hours.....	4	13	76 per cent.
Over 24 hours.....	4	28	87 per cent.
Not stated.....	1	5	.....
Total.....	23	55	71 per cent.

Diagnosis.—What are then the essential points in early diagnosis, for here lies really the secret of success? There is almost invariably a history of gastric trouble, though not necessarily a well-marked history of gastric ulcer. There is an attack of sharp pain, referred usually to the epigastric or left hypochondriac regions, followed sometimes by pain in the lower abdomen. The pain is at first intense often producing collapse or unconsciousness, or even death. Usually it quickly moderates.

Vomiting may or may not be present. Vomiting of blood is very unusual. In one case hematemesis had been present for many days; but although the vomiting continued after the perforation, it was without blood. After some hours, the time varying according to the amount and character of the escaped gastric contents, the symptoms of peritonitis manifest themselves.

The physical examination of the patient is of great importance. In the earliest stage of the trouble the pallor, the anxious countenance, the feeble pulse, the thoracic respiration,[1] and the rigid abdomen, all point to the injury to the peritoneum. Just as in beginning appendicitis abdominal rigidity is sometimes more marked on the side where the lesion is situated, so in perforation of the stomach the abdominal muscles of the left side are apt to be more tense than those of the right side. If the stomach were empty, or nearly so, when perforation occurred palpation of the abdomen would only serve to locate the tenderness, and show the rigidity of the muscles. If a large amount of fluid has escaped from the stomach, its presence may be demonstrated by the usual tests for gastric fluid. In certain cases the induration in the wall of the stomach about an ulcer, makes a tumor which can be felt by abdominal palpation. This is worth remembering in this connection, although the tenseness of the abdominal muscles in perforation make deep palpation difficult.

If gas has escaped from the stomach or has developed by fermentation of the escaped gastric contents, the hepatic and splenic dulness may be reduced in area, or wholly disappear. It is evident that this condition might also follow intestinal perforation. But when the abdomen is opened the distinction between the two is plain, for the gas from the stomach is without odor, or slightly sour, while that from the intestines has a fecal odor.

Comte,[1] whose article on gastric troubles will well repay perusal, says that perforation of the stomach is most easily confounded with acute intestinal obstruction, but that fecal or fecaloid vomiting is usually present in the latter trouble.

Perforation may also be confounded with an attack of pain in a gastric ulcer, which has not perforated, as the following interesting history of one of Jower's[2] cases shows. It is just such facts which make one skeptical concerning the cases of perforation (?) which are treated successfully by rest in bed and rectal feeding.

Twelve days after operation (for perforated gastric ulcer in the posterior wall, which had been duly sutured) the patient was doing well and taking three ounces of milk and three ounces of mut ton broth alternately every two hours. In the morning of that day she complained of pain in the region of the stomach, going through to the back, and smaller quantities of food were given. About 1 P.M. the patient suddenly complained of intense pain in the region of the wound, and "spreading all over the stomach," as she expressed it. The abdomen was flat, but did not move with respiration. Half an hour later, as the patient was considerably worse, Jowers opened the abdomen and found the stomach adherent to the wound in the abdominal wall, and at the site of the sewn ulcer to the posterior wall of the lesser cavity of the peritoneum. There was no evidence of new perforation nor of peritonitis. Half a pint of milk injected into the stomach did not escape, and was washed out and the wound closed over a drainage tube. The patient recovered. One month later she had a similar, though lighter attack, which was relieved by morphia.

(To be concluded.)

[1] Possibly Litten's "diaphragm phenomenon" (New York *Med. Record*, 1895, ii, p. 901) may be absent on the left side, especially if any effusion has already occurred to paralyze or impair the diaphragm. At any rate it is a sign worth looking for.

HYDROTHERAPY IN TYPHOID FEVER.

By SIMON BARUCH, M.D.
OF NEW YORK.

The Medical News of February 8, 1896, contains an article on this subject, which may mislead by its *ad captandum* arguments, and which it may therefore be profitable to analyze and discuss in the interest of therapeutics. The author does not claim any practical experience with the Brand method, on the contrary, he "confesses to a prejudice against the immersion treatment of typhoid fever." But he is correct in the statement that "*an overwhelming majority of the profession is against the method.*" Being convinced by earnest investigation for five years that "the majority of the profession" is, as a rule, biased by the same ideas and prejudices, which pervade the article, and as a proper presentation of the latter may serve to dispel some of the mist that seems to envelop the ordinary conception of the *rationale* of hydrotherapy, it may be profitable and interesting to analyze this author's views and conclusions, and extract their logical gist, without wearying the reader with polemics.

The author starts out with the statements that, with rare exceptions, at "present all typhoid patients in hospitals in this country are treated by immersion, and all the private patients by methods that are hydrotherapeutic only to the extent of cool sponging; and that, although most expressions of opinion heard in societies or read in journals, favor the Brand treatment, a secret ballot would show an overwhelming majority of the profession against this method." This may be true; but it is not reasonable to presume that men like "*Osler and other eminent clinicians*," would "enthusiastically indorse" a method of treatment that has so little to commend it. These gentlemen mold the minds of the rising generation of physicians; they have large clinical material under the strict supervision of intelligent assistants, and they may therefore be accepted as reliable guides to the general practitioner. The cause of the overwhelming "secret ballot," which would be cast against the Brand method by "practitioners in the small towns," is not to be sought, as the author curiously enough claims, in their having "not only relatively, but absolutely better opportunities for studying typhoid than city physicians;" but in the fact that they rarely have the opportunity or the facilities for the bath treatment, and that they are generally prejudiced against it by reason of inexperience. That it is impossible to form a correct judgment of the comparative value of two methods of treatment unless both are practised under approximately similar conditions, goes without saying.

Since 1889, only three *outspoken* opponents have been encountered besides this author, and the first of these has seen the error of his way. These gentlemen did not claim to have any personal experience with the method. They frankly expressed a prejudice against it, just as the author has done. I would not impugn the sincerity of the advocates on the adverse side, but I must protest against deductions not drawn from actual experience. That one positive witness with experience is worth all the theoretical and sentimental negations that may be marshaled will be conceded by the fair-minded reader.

The author concludes from his observations that "bathing oftener than twice daily would produce depression in all but the most robust; that fifteen minutes is the proper limit of the bath; that boys often grow livid, and are enfeebled by bathing, etc." The reader must decide for himself how far these conclusions may be accepted. Then he may be able to answer the author's question. "Can it be expected that the typhoid fever patient would receive all the benefit from immersion that a healthy person gains and be immune from the possible disadvantages? The advocates of immersion practically answer this question in the affirmative," says the author. This seems to be of slight moment, however, for he simply brushes it aside and proceeds to make a comparison between the Brand bath and the swimming exploits of healthy persons from four to seventy years of age. He argues that the former must be injurious because "it is as cold and as long-continued as the latter, and is repeated two to four times as often as that which a healthy swimmer of average vigor can endure without depression; the typhoid patient has not the benefit of exercise during or after the bath," etc. "The fact that depression follows a course of bathing without obvious chilling (in the healthy), is well established" in the author's mind. Such is the drift of his argument.

Even if the proposition regarding the depressing effects of a course of bathing in health, could receive acceptance, it would be illogical to apply observations made on boys (the majority of his subjects), who are apt to exhaust their reactive capacity by pranks, before, during, and after swimming under a hot sun, in the open air, and in water of 70 to 80°, to fever patients, most of whom are adults, who are quietly placed into the tub, who are well rubbed by two attendants, who are in addition stimulated by brandy before the bath, and well

dried and wrapped up after it. Such a comparison needs but to be stated to be its own refutation. Moreover, if there is anything positively established it is the tonic effect upon the heart of a Brand bath *properly administered*. The pulse almost always becomes less compressible, less frequent, and loses its dicrotism; the respiration is deepened and slowed. All this was illustrated on page 224 of the Medical News, February 22, 1896.

The same nonchalance with which the author dismisses the denial of unfavorable effects of the Brand bath by the advocates of the latter, characterizes his denial of the value of the "magnificent accumulation of statistics." He reminds the reader of the misleading character of numbers, and of the tendency of advocates to doctor the returns in the interest of preconceived notions, etc. In his zeal for "conservatism," he does not hesitate even to "doubt the good faith of some who practice immersion in hospitals, but who do not urge it upon their private patients." That all this is written in lieu of actual evidence, is patent from the fact he frankly admits that "it is not possible at the present time to refute the case reports of hospital attendants, nor to show that the *post hoc, ergo propter hoc* fallacy has been committed."

That figures may mislead is doubtless true; but it happens that there are some statistics in typhoid fever that cannot mislead. These were not made by the originator of the Brand method, but by a man, occupying a high military position, Dr. A. Vogl, the chief of the medical staff at Munich.

Without entering into details, this painstaking search of the records of forty years of a hospital governed by strict military discipline shows, that a reduction of mortality from an average of twenty per cent. under all kinds of treatment, and during epidemics of different intensities, to 2.7 per cent. under Brand baths. Dr. Vogl summarizes these excellent comparative statistics as follows:

DIVISION II.

Cases.	Treatment.	Mortality.
5884	Expectant, 1841–78,	20.7 per cent.
2841	Expectant and bath combined, 1868–81,	12.2 per cent.
702	Strict cold baths and antipyretics, 1877–87,	7.6 per cent.
144	Strict cold baths and less antipyretics, 1882–89,	4.1 per cent.

DIVISION I.

428	Strict cold baths, 1880	2.7 per cent.

Excluding all other statistics these alone protect the Brand method against carping criticism, unfounded skepticism, and baseless prejudice. By these statistics carefully studied, I was convinced of the folly of my own prejudice; there cannot be a reasonable doubt cast upon a military record of eight thousand cases, prolonged through forty years. In the "Uses of Water in Modern Medicine," page 109, Volume II, I have presented a table of comparative statistics which furnishes an instructive view of this whole question. To this may be added the following statistics, presented by the translator of my book in the German edition.

FROM GERMAN SOURCES.

	Mortality.
Jürgenson, Tübingen, under expectant treatment,	22.1 per cent.
" " faulty bath treatment,	7.1 per cent.
" " strict " "	1.8 per cent.
Brand, Stettin, " " " "	3.5 per cent.
Leichtenstein, Stettin, " " " "	5.4 per cent.
Ratjen, Hamburg, " " " "	4.0 per cent.
Drasche, Vienna, " " " "	9.3 per cent.
Before " " " "	16.2 per cent.

FROM FRENCH SOURCES.

Tripier & Bouveret, Lyon, before bath treatment,	25.0 per cent.
" " " under " "	7.5 per cent.
Richard, in 38 cases, " " "	5.2 per cent.
Jubel-Renoy, expectant treatment,	14.2 per cent.
collective report under bath treatment,	7.3 per cent.
own cases under strict bath,	4.7 per cent.

FROM AMERICAN SOURCES.

Dr. Kelly, Philadelphia, before bath treatment,	17.0 per cent.
after introduction of "	4.5 per cent.
Dr. Elliot, Philadelphia, before bath "	24.0 per cent.
after bath treatment, since 1891,	7.4 per cent.
Dr. Thompson, New York, before bath treatment,	19.0 per cent.
after " "	7.0 per cent.

Among the remarkable italicized propositions submitted in the author's article is No. 4: "The cold bath removes comparatively little excrementitious matter from the body, it checks the tendency to sweating and throws the flow inward to organs already infiltrated or irritated by toxic principles." This *ex cathedra* statement is not supported by any evidence furnished, either by the author's observation or that of others. And it is directly contradicted by the exact experiments of Roque and Weil, who found that the urotoxic coefficient of the urine in patients suffering from typhoid fever is decreased; that while the coal tar antipyretics still more diminish it, the cold bath, increases it very materially—threefold in some experiments. That the blood is not "thrown inward" as the author fears,[1] is proved by the ruddy hue of the skin of the patient when emerging from a properly administered Brand bath. "In conclusion let me say that I am not writing to support a theory, nor to assail the advocates of an opposite theory, but to elicit the truth. I am open to correction and ready to acknowledge an error." These words of the author I heartily re-echo, for if any equally successful method of treating typhoid fever were devised, I would gladly abandon the justly unpopu-

[1] A recent editorial in the *Philadelphia Medical and Surgical Reporter*, quoted in the *Medical Record*, reiterates this fallacy, which cannot be too earnestly contradicted.

lar cold bath. Until this is done, it is our bounden duty to save lives by overcoming the prejudices and objections of its opponents.

The enthusiastic advocacy of the Brand bath with which I am credited is not due to the recognition of its merits only. A large share is due to the fact of which Brand himself has jocularly reminded me, viz., that my prejudice against it found expression in the Academy of Medicine, where I said in 1887, "The cold bath may be adapted to the German soldier, but it is too severe for the average American citizen." Having myself been a doubting Thomas, and being convinced that I was in error, I am the more desirous of making amends.

In conclusion it may be of interest to quote from a recent letter of Dr. A. Vogl, the medical director of the army at Munich, whose statistical records have been quoted above. Under date of the 20th of February, Dr. Vogl writes me: "I regret very much that the Brand method is not yet universally acknowledged, especially as none of the opponents have thoroughly tested it. We use it in the army whenever opportunity presents, with the best results, never over four per cent. mortality. Your recognition of its value is gratifying. The adverse position of the profession toward hydrotherapy injures the respect for our science; it would not otherwise be possible that so crude a water quack as 'Father Kneipp,' could maintain his position. In many desperate cases this empiric has obtained successes, which cannot be denied, and in cases in which physicians had tried all medicinal agents, but not even a cold compress."

In this country too, the medical profession will lose much vantage ground, if it continues to neglect hydrotherapy in chronic diseases, in which its effect is just as striking as in typhoid fever. How much more favorable the results would be if physicians would give attention to the *rationale* and applications of water in the treatment of disease, and not entrust it, as is but too frequently is done, to bath attendants and nurses, who possess only the most superficial, crude, and mechanical knowledge of the subject? Hydrotherapy should be applied in chronic diseases as it is in typhoid, under the frequent supervision of the medical attendant. The technic should be adapted to the condition of the patient and the indications of each case, which are liable to change, and which cannot be appreciated by bath attendants, no matter how familiar they may claim to be with the treatment. These water-cure establishments, not under skilled medical supervision, should be avoided. This may be the more readily done now, because several institutions exist in the city and are beginning to spring up in other medical centres, in which not alone the well-to-do, but also the poor may obtain a judicious hydrotherapy *under supervision of physicians*. The importance of an exact technic was emphasized in my paper before the Philadelphia County Medical Society, a report of which may be found in the Medical News of February 22, 1896.

CLINICAL MEMORANDUM.

CALOMEL AS A SPECIFIC IN DIPHTHERIA.

By LAWRENCE F. FLICK, M.D.,
of Philadelphia.

Mercury, among drugs, has held for years the first place in the treatment of diphtheria. Old time practitioners were loud in their praises of the yellow sulphate of mercury in the treatment of croup. In more modern times most excellent results have been reported from the use of corrosive sublimate, and in the hands of some, this preparation has given almost specific results. The fear of using large doses of corrosive sublimate, and large doses have been insisted upon by those who have reported success with the treatment, has no doubt stood in the way of a general adoption of this plan of treatment. At any rate the mortality from diphtheria has so persistently kept up under drug treatment that antitoxin has been welcomed as a substitute for all drugs in our contest with this disease.

In the applause for antitoxin it may not be out of place to call attention to such drugs as can be advantageously and safely used, if not alone, at least with antitoxin, for there remains yet a large mortality to overcome in diphtheria, in spite of the good results from the serum therapy.

Ever since the modern views about the use of mercury in diphtheria have been advanced, I have used the drug constantly, in some form, in the treatment of this disease. I have usually obtained good results but also have had failures. Somehow I have gradually drifted toward the use of calomel, and have come to employ it with rather surprising results. The method which I now follow entirely and with a certain precision, is to give calomel in very minute doses at short intervals. I administer from $\frac{1}{60}$ to $\frac{1}{120}$ of a grain of calomel, rubbed up with sugar or sugar of milk, every fifteen minutes to every half hour, dry on the tongue. This constitutes an easy and pleasant method of administration. The treatment is kept up day and night until all evidences of the disease have disappeared. The result in my hands has been so magical that I have myself been skeptical many times about my diagnosis. Since I have adopted this method of treating diphtheria, now nearly two years ago, I have not had a death from the disease, nor indeed a serious complication. I fully appreciate the fact, in connection with this statement, that my experience may mean very little, as I have not seen a very large number of cases,

tunities, to determine whether or not the method is worthy of recognition. I therefore make this report in the hope that it will be tried cautiously and condemned if found wanting.

MEDICAL PROGRESS.

Spontaneous Disappearance of an Inoperable Malignant Neoplasm of the Bladder.—SCHUCHARDT (*Deutsche medicinische Wochenschrift*, 1896, No. 9, p. 133) has reported the case of a man, fifty-seven years old, who for four years had suffered from difficulty in micturition, without pain. The urine, at times, appeared bloody; and for six weeks it had been turbid and stinking. There were pains in the hypogastrium; at times headache, constipation, emaciation, debility, cough, and expectoration. The appearance cachectic, but there was no fever or acceleration of pulse. The respiration was a little quickened and superficial. The pulmonary resonance was preserved and auscultation revealed bronchial râles. The expectoration was muco-purulent and copious, but contained no tubercle bacilli. Above the symphisis pubis was a prominence about as large as an ostrich egg, of firm consistence, and in close relation with the abdominal wall, particularly on the left. The overlying tissues appeared to be adherent, and only slightly movable upon the tumor beneath. Through the rectum a globular mass could be felt, almost filling the pelvis, and compressing the rectum. The prostate could be felt apart from the tumor, and behind it was a transverse fissure separating the two. Upon catheterization the lumen of the bladder was found greatly contracted. The urine was almost purulent and possessed an ammoniacal odor. A diagnosis of malignant neoplasm of the bladder was made and celiotomy undertaken. The rectus muscle was found infiltrated with nodules, varying in size up to a hazelnut, upon section presenting a medullary, homogeneous grayish-white appearance. The bladder was represented by a firm, nodular tumor, as large as two fists, free posteriorly, but adherent anteriorly and laterally. Upon the left the tumor was adherent to a loop of small intestine and in the immediate neighborhood the peritoneum was infiltrated with nodules of new formation The tissues of the pelvis were also involved, particularly on the left, where the iliac artery was surrounded by new growth. In view of all these facts, the removal of the tumor was not attempted, and the wound was closed as well as it could be, a portion, however, remaining open. The patient was collapsed for several days after the operation, and the temperature remained above the normal for three weeks. Suppuration took place in the wound and continued for some time, ceasing after the removal of some unabsorbed ligatures. Finally, however, the wound closed and the patient improved in weight, nutrition and general condition, being dismissed cured six months after the operation, and so continuing three months later, at the time of last report. It is to be regretted that an examination was not made to determine absolutely the nature of the neoplasm, and of the micro-organisms present in the pus discharged from the wound.

and my cases may all have been very mild. The majority of cases of throat trouble that come under my notice come early, before any membrane has formed. Hence, whilst I treat the usual percentage of throat cases that go with a fair-sized practice, I rarely have cases that have advanced to the stage of membranous deposit. However, the same happy results have been obtained in cases in which the presence of the bacilli had been determined by the bacteriological department of our city. I will relate three such:

M. S., aged eight years. Had been sick four or five days when I was called in. Found membrane lining fauces and pillars on both sides. Could not speak above a whisper; clammy sweats at intervals; no fever; poor pulse, but only slightly above normal in number. Gave $\frac{1}{60}$ grain calomel dry on tongue every fifteen minutes for forty-eight hours. Gave gargle of tannic acid and chlorate of potash in glycerin and rose water. At end of forty-eight hours membrane had all disappeared. Reduced dose of calomel to $\frac{1}{100}$ grain. Kept up treatment for a week. After second day gave some tincture of the chloride of iron, brandy, and tincture of nux vomica. At end of week voice had returned and all symptoms had practically disappeared. At end of two weeks bacteriological department reported no bacilli present.

F. S., aged five years. Began with fever, restlessness, and a very croupy cough; slight membrane visible on one tonsil. Bacilli reported present by bacteriological department. Gave calomel $\frac{1}{60}$ grain every fifteen minutes. Used same gargle as above. At end of twenty-four hours patient coughed up a well-formed membrane. Coughed severely for twenty-four hours more, but at the end of forty-eight hours all symptoms had disappeared and patient was convalescent. Kept up calomel in small doses and gave tincture of iron, brandy, and tincture of nux vomica. At the end of ten days bacteriological department reported no bacilli.

L. S., aged three years. Was taken with very high fever. Follicles of tonsils filled up, and tonsils and pharynx were swollen and red. Diphtheria bacilli were found by bacteriological department. Gave calomel $\frac{1}{60}$ grain every fifteen minutes and no other treatment. At end of twenty-four hours fever had disappeared. Gave the medicine less frequently and fever returned. Again gave it every fifteen minutes. At end of forty-eight hours all acute symptoms had disappeared. Decreased the dose to $\frac{1}{120}$ grain and gave at intervals of half hour, and later used the brandy, iron, and nux vomica. Improvement was rapid and recovery prompt.

Fully appreciating the danger of being oversanguine about results in any treatment of disease, and realizing that harm can be done by inducing others to take up a method which may fail in their hands and thus lead to loss of life, which might have been saved by other methods, I make this brief report with much reluctance. On the other hand, I have had such uniformly good results in many cases of throat trouble, which in the beginning looked like diphtheria, and also in successfully relieving cases of undoubted diphtheria, that I have felt it my duty to permit others, with better oppor-

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to The Medical News will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 Fifth Avenue (corner of 18th St.), New York.

Subscription Price, including postage in U. S. and Canada.

COLLECTIVE INVESTIGATION.

Accurately observed and recorded facts within one's own sphere of observation contribute more to the advance of medical science than any amount of philosophizing from the limited experience of any one individual. And when these recorded facts are brought together from the personal experience of a large body of well-trained observers, the best possible condition exists for reaching wise conclusions.

The American Pediatric Society has, for several years past, pursued this plan of investigation, and the result has been not only to make a most interesting and profitable meeting for those present, but to establish a certain high rank of scientific excellence for the Society, and to settle for the whole profession some vexed and important questions. This year the Society asks its members to take up the subject of antitoxin treatment of diphtheria in private practise, and to report to the Society their careful observations upon certain important designated facts. It is a well-recognized principle that the results of hospital treatment differ widely from the same methods when applied in private practise, and the object of this investigation is to determine how successful, or how much of a failure, the antitoxin treatment of diphtheria has proved in the hands of general practitioners in their private work. The Society appeals to the whole profession, and each and every one who has had experience, in one or more cases, of the application of the antitoxin treatment, is requested to send in responses to the questions that appear in their circular, and which are reproduced in another column.

It is an encouraging sign to note that other societies have taken up this same method of study, and are putting it into active application. The Wisconsin State Medical Society, which meets in Madison, Wis., June 3d, 4th, and 5th of this year, will devote its entire session to the subject of preventive medicine. An effort has been made on the part of the president and the committee in charge to convert the whole medical profession of the State into a body of sanitarians. In a circular issued early in the year the whole regular profession were asked to be on the alert and take careful observation upon all points relating to hygiene and sanitation that might come within their observation. This had special reference to the pollution of water supply, contamination of the air, the adulteration of food, faulty methods of education and training of children, etc., etc. It is therefore expected, as the invitation announces, there will be "a rattle of musketry all along the lines against the unsanitary conditions and customs prevailing throughout the State." We predict for the Wisconsin State Medical Society a most interesting and profitable meeting, and extend to them our hearty congratulations on the enterprise with which they have undertaken this investigation.

ORTHOPEDIC SURGERY.

A CRITICAL RESUME OF RECENT PROGRESS.

One of the most evident advances in the management of chronic disability has been made recently in the effective treatment of congenital dislocation of the hip-joint. Although the anatomical conditions which are present as accompaniments or results of the deformity are now well known, its ultimate cause is likely to remain a mystery until an explanation of the clinical fact that up-

ward of ninety per cent. of the cases occur in females is offered.

The functional awkwardness, the evident insecurity and deformity, the discomfort, weakness, and pain that become more evident with the increasing weight of the body and strain of use, attracted attention to the importance of the disability in ancient times. It was described, and treatment was suggested by Hippocrates, Galen, Paré, and others of the older writers, and in 1829 Dupuytren, after a careful study of the anatomy and symptoms of the deformity, asserted that it was not only incurable, but that effective palliation was hardly attainable.

The term dislocation suggests, naturally, that the only effective treatment must be a replacement of the displaced bone. From this standpoint, an enumeration of some of the means used to attain this object, or to remedy the effects of the deformity, may be of interest, and will at least illustrate a diffusion of energy that may have postponed the solution of the problem of rational treatment.

1. To check the progress of the deformity, corsets and pelvic girdles have been used to exert pressure on the prominent trochanters.—Stromeyer, Lannelonge, Heine.

2. The weight of the body has been removed from the yielding capsule by the crutch action of a leg-brace. This, when combined with traction, or otherwise modified, has long been the most generally accepted form of treatment.—Hessing, Sayre, Schede.

3. Gradual reduction of the upward dislocation of the femur by long-continued traction and confinement to bed, followed by the use of retentive apparatus.—Humbert, Pravaz, Adams, Brown.

4. Traction at night only.—Volkmann.

5. Traction, forcible manipulation, and subcutaneous tenotomy. In 1841 Guérin advocated a method of preliminary traction: subcutaneous division of muscles and ligaments, forcible manipulation and scarification of the head of the femur and adjoining parts, for the purpose of exciting adhesive and retentive changes. A similar procedure has been suggested recently by Shaffer.

6. Forcible, immediate reduction of the dislocation by methodical manipulations.—Paci.

7. Forcible manipulation, subcutaneous division of resistant tissues, and subcutaneous enlargement of the acetabulum.—Brodhurst.

8. The injection of solution of chlorid of zinc, with the aim of exciting a retentive barrier above the head of the bone—*méthode sclérogène.*—Lannelongue.

9. Open operation, division of contracted tissues, with formation of a periosteal flap from the ilium to cover the head of the bone.—König.

10. Resection of the head of the femur and formation of a similar periosteal flap.—Hüter.

11. Resection of the head of the femur.—Roser, Reyher, Mollière.

12. Resection of the upper extremity of the femur and implantation of the stump in depression hollowed in the ilium.—Ogston.

13. Nailing the femur to the ilium.—Da Paoli.

14. Osteotomy of the femur on the sound side to adapt it to the deformity.—Mayer.

In 1890 the great advance toward ulimate cure by definitely carrying out the ideal treatment of a dislocation—replacement—was instituted by Hoffa. At this time, notwithstanding the various efforts enumerated above by some of which an occasional case had been benefited or cured, the prognosis, practically, was as hopeless as it was when Dupuytren pronounced it an incurable deformity.

Hoffa's theory as to the chief obstacle to reduction of the deformity was incorrect, and the technic of his operation has been greatly modified, but the credit of this great advance is his. He first attacked the problem with a definite and reasonable purposein view, and demonstrated its feasibility.

By the work of Lorenz and Hoffa, the anatomy of the deformity has been made clear; the obstacles to reposition that are present, either in the head of the femur, the size of the rudimentary acetabulum, or the changes in the capsule or other tissues are now known, and it is because they are known that the principles of treatment may be rationally judged.

This treatment, in the future, if it aims at ultimate cure, is likely to be limited to two modes of procedure, although the ultimate design is the same in both, viz.: (1) The replacement of the dislocation, without open operation, in the younger subjects, and when the secondary changes will

allow, by the method of Paci, or by the more comprehensive and reasonable procedure of Lorenz,—what he calls the functional weighting method (*functionelle belastungsmethode*). This is the result of its author's numerous experiments and practical experience in the largest number of open operations for the relief of the condition performed by any surgeon. It is not only a more effective means of reduction than that of Paci, but its use is rigidly restricted by an age limit, within which practical experience has demonstrated its feasibility. (2) For the more advanced and difficult class of deformity in which section of the hypertrophied capsule and enlargement of the deficient acetabulum may be necessary, the Hoffa-Lorenz operation will remain as the method of necessity.

Now that the disability has been removed at last from the list of incurable deformities, the more serious operation is likely to become less necessary; for as the attention of many workers becomes directed toward a definite system of treatment, with a definite object in view, which may be attained in a definite time, the importance of early treatment of the condition will be generally recognized by parents and physicians. Thus the indifference or the mistrust regarding treatment and the disbelief in the possibility of cure which exists at present, and which is the chief obstacle to its successful demonstration, will be overcome.

It is, perhaps, hardly necessary to add that, although the reduction of the dislocation is the essential preliminary of ultimate cure, yet the deformity habit remains, and will continue until the weakness of disused muscles has been overcome and until the body has adapted itself to the new conditions. For these reasons, careful and long-continued after-treatment and supervision will still remain essential to complete success.

Royal Whitman, M.D.

ECHOES AND NEWS.

The wave of measels, which has been passing over New York city, is still at high-water mark; but if the pleasant weather continues the Health Department officials expect it to subside. For the week ending April 11, 493 cases were reported, as against 426 cases the previous week. This, however, is a slight decrease from the average weekly report for March.

The public bequests under the will of the late Mrs. Josiah Vose divides the handsome sum of $380,000 among the charitable institutions of Boston.

From Pittsburg it is reported that Mr. H. C. Frick will build on a plot of ground containing about forty acres a hospital for children. The building is to cost not less than $500,000, and will be maintained in the most liberal manner.

The Philadelphia Board of Charities and Correction elected Dr. Charles W. Burr neurologist, to fill the vacancy in the medical staff of the Philadelphia Hospital, created by the resignation of Dr. Wharton Sinkler. Dr. B. F. Stahl and Dr. J. H. Gibbon were made nervous and surgical registrars respectively.

The Massachusetts Charitable Eye and Ear Infirmary is appealing to the State for $100,000 to assist in purchasing a site for its new building.

The popularity and value of the X-ray is still increasing. The charming young lady who recently expressed at a dinner party such admiration for the penetrating qualities of the cathode rays, has now named her latest culinary production the Röntgen pudding. Let all wise men beware!

The House Military Committee has ordered a favorable report on the bill giving to veterinary surgeons of the army the rank of Second Lieutenants of Cavalry. It provides, however, that the surgeons so promoted shall be graduates of veterinary colleges.

Dr. Thomas Herbert Brickerman, a prominent oculist of Liverpool, England, is visiting relatives in Philadelphia.

The American Laryngological, Rhinological, and Otological Society held its second annual meeting at the New York Academy of Medicine, on the 17th and 18th instants. The inherent strength of this young but talented body is evident in the careful management of its business affairs, the earnestness and harmony of its members, and the high literary and scientific character of its proceedings. This meeting was a marked success. Dr. Frank Hyatt of Baltimore, was elected president; Dr. Fred. L. Jack of Boston, vice-president and chairman of the eastern section; Dr. J. S. Maborn of Pittsburg, vice-president and chairman of the middle section; Dr. Jas. E. Logan of Kansas City, vice-president and chairman of the western section; Dr. Wm. Scheppegrell of New Orleans, vice-president and chairman of the southern section, and Dr. Robert C. Myles of New York, secretary and treasurer.

The University of Michigan is considering an extension of its medical course to six years, to correspond with the requirements of Harvard. It is found that many of the students in the former university at present combine their literary and medical courses in such a manner that the

two are completed in this time. It is proposed to make this obligatory, which will necessitate each graduate in medicine holding a literary degree as well.

Dr. Woods Hutchinson, Professor of Anatomy, State University of Iowa, has been elected Lecturer upon "Comparative Pathology and the Ancestry of Disease" in the Medical Department of the University of Buffalo.

At the meeting of the Tennessee State Society, Dr. G. W. Drake of Chattanooga, was elected president; Dr. T. R. Moss of Dyersburg, Dr. W. F. Clary of Bellbuckle, and Dr. J. B. F. Dice of Morristown, vice-presidents for Western, Middle, and Eastern Tennessee, respectively; Dr. C. R. Atchison of Nashville, secretary; and Dr. D. E. Nelson of Chattanooga, treasurer. The next meeting will be held in Nashville, commencing the second Tuesday in May, 1897.

The current number of the *British Medical Journal*, remarking upon the notable unanimity of the lay press in insisting upon the absolute sacredness of professional confidences, is led to point out the flagrant want of consistency in the English courts of justice regarding this question. Before one judge, damages may be found for revealing a professional secret, while another will hold a witness for contempt who refuses to violate such a confidence. Again, it is urged that the lips of a medical man might be sealed to his own or his family's disadvantage by a professional consultation imposed for exactly this ulterior motive. It is not impossible that much ultimate benefit may be reaped from the Kitson-Playfair trial in the final adjustment of this vexed problem. "The medical profession would be more than glad to accept the most rigorous ruling as to the inviolability of professional confidence, for this would greatly simplify their position. All they want is to have a definite law for their guidance, and to be protected against the discordant decisions of judges and the vagaries of impressionable juries and journalists."

There was a case at Montpellier some years ago, which, though far more dramatic than the Kitson-Playfair one, resembled the latter in that it largely turned on the revelation of professional secrets. A doctor of medicine at Montpellier was consulted by a mother as to one of his patients who was a suitor for her daughter's hand. The doctor at first gave an evasive answer to the questions put to him, but when the lady point blank asked him whether, as the father of a family, he would give his daughter to the young man, he felt constrained to reply in the negative. As the result of this communication the marriage was broken off. Some days later the doctor's carriage drove up to the local school of medicine, which he was in the habit of attending, without either the physician or his coachman. Search was at once made, and the unfortunate men were found lying dead on the road some distance away. For a time the origin of the crime was wrapped in mystery, but eventually the act was traced to the disappointed suitor, who, however, had blown out his own brains before the discovery was made.—*The Paris Messenger.*

As announced some time ago, the death of Dr. Wilhelm Meyer, of Copenhagen, who first called attention to the condition known as adenoid hypertrophy at the vault of the pharynx, and described the efficient means for its relief, has been followed by a movement of an unusual nature. It is proposed to erect a monument to Dr. Meyer in Copenhagen by subscription collected all over the civilized world from physicians interested in the operation for the removal of adenoids, and from patients who have been relieved by it. The cost of such a monument in Copenhagen is about one-quarter of what it would be here. For the furtherance of the enterprise an international committee was formed in Europe, the members of which are the presidents of the various national associations of laryngology. The representative upon the international committee for the United States is Dr. Wm. H. Daly. Dr. Daly has appointed a national committee for this country with Dr. D. Bryson Delavan as chairman, and as active members Drs. Harrison Allen, Philadelphia; C. E. Bean, St. Paul; J. H. Bryan, Washington; J. W. Farlow, Boston; F. W. Hinkel, Buffalo; J. E. Logan, Kansas City; A. Mathewson, Brooklyn; J. C. Mulhall, St. Louis; A. W. de Roaldes, New Orleans; C. W. Shields, Richmond; S. E. Solly, Colorado Springs; A. B. Thrasher, Cincinnati; H. E. Wagner, San Francisco; Gorham Bacon, New York; H. S. Birkett, Montreal; M. R. Brown, Chicago; T. R. French, Brooklyn; Samuel Johnston, Baltimore; J. H. Lowman, Cleveland; H. G. Miller, Providence; W. P. Porcher, Charleston; J. O. Roe, Rochester; E. L. Shurly, Detroit; H. L. Swain, New Haven; M. R. Ward, Pittsburg; C. V. Woolen, Indianapolis. Under the direction of the abovenamed gentlemen, who, it will be seen, have been selected to represent every part of the country, it is hoped that the collection of the desired amount of money will soon be accomplished. The treasurer for the New York division is Dr. Robert C. Myles, to whom, or to the chairman, Dr. Delavan, or to Dr. T. R. French of Brooklyn, subscriptions should be sent.

The Home Secretary recently refused abruptly to receive a deputation from the United Kingdoms Police Surgeons' Association, who wished to discuss with him an increase in the fees allowed medical witnesses. The evident injustice done medical men when required to appear in this capacity is by no means confined to Great Britian, where the scale of awards is about double that of this country. In almost every State of the Union there exists a law which, at least in all criminal cases, compels a physician to desert his practise often without warning and with heavy pecuniary loss to himself, and it maybe danger to the welfare of his patients, to appear as a witness before any court in the commonwealth. He is detained at the pleasure of the judge, who in turn is hampered by those obstructive methods so well known to criminal lawyers. When released he finds his way home at his own expense, having received the royally handsome honorarium of from one to three dollars per diem. The possession of knowledge that places the professional man in such demand as a witness should be recognized and remunerated accordingly.

ANNOUNCEMENT.

COLLECTIVE INVESTIGATION OF THE ANTITOXIN TREATMENT OF DIPHTHERIA IN PRIVATE PRACTISE BY THE AMERICAN PEDIATRIC SOCIETY.

THE committee of this society, to which this matter has been referred, desires to place before the profession, for collective investigation, the subject of antitoxin treatment of diphtheria, the cases for the investigation to be collected entirely outside of hospital practise and published as the report of the society.

Two points are to be made prominent: First, the length of time elapsing between the first appearance of the disease and the administration of the serum antitoxin. This is to be stated as accurately as possible, even to fractions of a day. Second, the severity of the disease as shown by (*a*) extent of membrane; (*b*) general prostration; (*c*) involvement of the larynx.

We cordially invite the co-operation of members of the profession in this investigation, in return for which the society will mail to each contributor the full report when it is published. An abstract giving the main facts will, however, appear in the leading medical journals, immediately after the meeting of the society in May.

Please fill out the accompanying blank and return it *at your earliest convenience* either to the president or the secretary of the society. Cases received after May 1st cannot be included in the society's report.

In behalf of the society,

JOSEPH O'DWYER, M.D., *President*,
967 Lexington Ave., New York City.
SAMUEL S. ADAMS, M.D., *Secretary*,
1 Dupont Circle, Washington, D. C.
L. EMMET HOLT, M.D.,
WILLIAM P. NORTHRUP, M.D.,
Executive Committee of the Council.

Please reply to the following inquiries; if it is not possible to answer all of them, answer such as are positively known, even if but two or three:

1. Age?..... Sex?.....
2. Condition—Good?.... Fair?.... Bad?.....
3. Time in fractions of a day, if known, from first appearance of the disease to first injection?..
4. Was diagnosis confirmed by culture?.....
5. Number of injections made?.....
6. Extent of membrane—Tonsils?..... .....
   Nose?.....
   Pharynx?.....
   Larynx?.....
7. Operation—Intubation?.....
   Tracheotomy?.....
8. Complications or Sequelæ—Broncho-pneumonia?.
   Nephritis?.....
   Sepsis?.....
   Paralysis?.....
9. Result?.....
10. Remarks; including other treatment, kind of antitoxin used, general impressions regarding the case, etc.....
11. Name of reporter.....M.D.
    Address.....

SOCIETY PROCEEDINGS.

TRI-STATE MEDICAL SOCIETY OF IOWA, ILLINOIS, AND MISSOURI.

Abstract of the Proceedings of the Fourth Annual Meeting, held in Chicago, April 7, 8, and 9, 1896.

THE Society met at the Great Northern Hotel, and was called to order by the president, Dr. R. H. Babcock, of Chicago.

After the reading of the minutes of the last meeting by the secretary, the report of the treasurer, and reports of standing committees, the president delivered his address. He selected for his subject Antitoxin, or Serum Therapy.

He said the crowning achievement in this line of research had come through the chemistry of bacteriology. Nuttall conclusively demonstrated in 1888 the power possessed by the blood serum of combating the poisonous products of bacterial growth, but to Behring and Kitasato, in 1891, belonged the credit of having found a practical means of utilizing antitoxins in the treatment of disease. To those who decry the antitoxin treatment of diphtheria as dangerous, and its advantages as not yet proven, Dr. Babcock commended the criticism by Welch in the *Johns Hopkins Bulletin* of October, 1895. His (Welch's) analysis of cases treated and published up to that time, sets at rest all doubt concerning the great reduction in mortality accomplished by this treatment, and renders the physician culpable who refuses this remedy to his patients. Sufficient experiments on lower animals, and trials on human beings had already been recorded to warrant the belief that we shall soon possess an effectual weapon against tetanus. Attempts had been made to treat typhoid fever patients, with serum obtained from dogs rendered immune, and from convalescents, but as yet observations were too few to warrant a more extended discussion of serum therapy in this class of cases.

Dr. Babcock then traced the efforts that had been made to combat tuberculosis by means of serum therapy, telling of the first discovery that certain animals possess comparative immunity from the disease. Detailing several experiments, he said a more intelligent use of tuberculin seemed to show that the early failures were due not solely to the inefficacy of the remedy, but to its injudicious employment in too large doses.

He next passed on to a personal trial of the remedy, citing the case of a young woman of twenty-one years, whose sister had died of pulmonary tuberculosis, and in whom well-marked signs of inactive disease existed in the right apex, the administration of antiphthisin for two months was followed by a gratifying disappearance of the malaise, nervousness, and occasional slight cough. He also treated a male, aged thirty-four, with satisfactory results.

Dr. Von Ruck had furnished Dr. Babcock with advanced sheets of a report, soon to be published, of one hundred and eighty-two cases of consumption in all stages treated with tuberculocidin and antiphthisin, in which recovery was obtained in thirty-two per cent. of the cases, arrest

or marked improvement in thirty per cent., and some improvement in sixteen per cent.

In closing, he said that whatever had been thus far accomplished, the field was broad and would repay painstaking investigation along the line of the antitoxin treatment of tuberculosis.

"SPECIAL EDUCATION AS A MEANS OF TREATMENT IN CHRONIC NEURASTHENIA."

This paper was read by Dr. J. F. Percy of Galesburg, Ill. Neurasthenia was considered the result of an imperfectly used and, therefore, improperly developed nerve organization. His treatment is to take patients out of and away from themselves, so to speak, and he knows no better way of doing this than to educate them as to the real facts back of their morbid tendencies. In his city there is an ably conducted kindergarten normal school, and when he has a neurasthenic woman he sends her, if possible, to this school to take the normal course there. The result has been that every case so treated has recovered. Moreover, he believes he has lifted the life of his patient to a higher level of thought and action. In one case the right ovary was buried in a mass of exudate beneath the uterus. Electricity, and especially pelvic massage, was practised for over a year with but little appreciable result. He stopped all treatment and insisted that the woman take a kindergarten normal course, which she did, and the result is that to-day she is well, so far as any morbid mental phenomena are concerned. The course of instruction should be carried out by competent teachers, setting at rest the nervous system, so far as receiving and being influenced by morbid impressions. The teaching should be suggestive rather than direct. It is necessary to classify the patients and instruct them by degrees. This plan, which he had merely hinted at, would do more for cases of neurasthenia than anything else of which he was cognizant.

"CANCER OF THE UTERUS COMPLICATED BY PREGNANCY; INDICATIONS FOR OPERATION."

Dr. A. H. Cordier, of Kansas City, Mo., followed with a paper upon this subject. The author reported a successful case of vaginal hysterectomy in a woman thirty-two years of age, the uterus being three months pregnant.

Of twenty-even cases tabulated by Dr. Vander Veer, of Albany, five died during labor undelivered, nine died during the puerperal period, three results not mentioned, and ten recovered, the mortality to mothers being sixty per cent. Another author reports thirty-four cases of cancer of the uterus, complicated by pregnancy, with a mortality of fifty-two per cent.

Dr. Cordier drew the following deductions: (1) Cancer of the cervix uteri, if left without surgical interferences, always kills. (2) The disease, in most instances, is primarily a local process. (3) Early hysterectomy will cure quite a percentage of these cases. (4.) The microscope, while a great diagnostic aid, is not infallible in its findings. (5) The experienced surgeon is warranted in resorting to an hysterectomy, even in doubtful cases. (6) All malignant pregnant uteri should be removed when seen, before the disease has advanced beyond the period of a probable cure.

DISCUSSION.

Dr. Ryan of Galesburg, cited an uncomplicated case of cancer of the cervix, which occurred in the hands of another practitioner, and in which the cervix was amputated, the patient being four months advanced in pregnancy. Following the operation she went on to full term, and the child was delivered without difficulty.

Dr. L. H. Dunning of Indianapolis, said that if he should find hardening of the cervix and the development of a neoplasm with the presence of discharges, sanguineous or offensive in character, even though the microscope failed to reveal positively the existence of malignant disease, he should be inclined to pursue the course recommended by the essayist. Relative to the advisability of removing the cervix alone, it might be done if the surgeon is certain that the epitheliomatous variety exists; yet the woman's life is in peril after the neoplasm is removed because of the scar tissue which remains. A case corroborative of this point was cited.

Dr. Rufus B. Hall of Cincinnati, thought the whole matter hinged upon the diagnosis. When the diagnosis was accurately made, it is perfectly clear what should be done. He favors total extirpation, believing that high amputation should only be done in exceptional cases.

Dr. D. C. Brockman of Ottumwa, Ia., emphasized the importance of early diagnosis. He believes the fault in these cases lies largely with the general practitioner, who does not understand the importance of irregular hemorrhages occurring in women approaching the menopause, and who prescribes a placebo at a time when a radical operation is needed.

Dr. Byron Robinson of Chicago, concurred with the essayist that the microscope alone was insufficient in many cases to enable the surgeon to make an accurate diagnosis of malignant disease of the cervix, and that more stress should be laid upon the clinical history of the case.

"DIFFUSE PELVIC INFLAMMATION."

This was the title of a paper contributed by Dr. L. H. Dunning of Indianapolis. Five cases were reported in which vaginal hysterectomy was resorted to for inflammatory disease of the uterus and appendages, after which the author summarized as follows: (1) In all of his cases except one, the uterus, on removal, was not found to be markedly diseased beyond a glandular endometritis. (2) In the two cases in which the uterus and appendages were fixed the operation was most difficult. The uterus in either case was little diseased. The chief pathological lesions were double pyosalpinx and pelvic peritonitis. The operation would have been easy and the results quite as good by the abdominal method. (3) In these cases the appendages were much more inaccessible and less open to ocular inspection than in the abdominal operation. (4) In his experience in clamp cases the pain after vaginal hysterectomy is greater the first two days than after celiotomy. (5) The systemic disturbances, as evidenced by the temperature and pulse rate, do not vary much in the two methods. The temperature after vaginal hysterec-

tomy is lower the first three or four days, but is higher after six to ten days, when the sloughs begin to give way, (6) In two cases in which ligatures were employed instead of clamps, abscesses in the stumps of the broad ligament followed, retarding the recovery of the patients. Many cases of abdominal section were done in the hospital during the same time, and in none of them did abscess appear. (7) In one case of the five prolapsus of the vaginal walls appeared a few weeks after the patient began to walk around. This was a ligature case. Such a prolapsus he had never witnessed in a forceps case. (8) In three of the cases the same pain and nervousness followed the recovery as sometimes witnessed in cases of abdominal section. In two of the cases the pain and nervousness passed off after several weeks, as it usually does after abdominal section.

DISCUSSION.

Dr. Rufus B. Hall said that women should be educated up to the point of avoiding septic infection, suppurating tubes and ovaries. The young men likewise should be educated to avoid gonorrhœa in order to prevent infecting their wives in future years. This being accomplished, gynecologists would have fewer pus tubes and diseased ovaries to remove.

Dr. T. J. Watkins of Chicago, believes there are cases which should be operated on by vaginal incision and drainage, while there are others in which the abdominal route was preferable. All large pus collections in the pelvis that could be opened and efficiently drained without entering the peritoneal cavity should be treated by incision and drainage through the vagina or above Poupart's ligament. Vaginal hysterectomy should be the operation of election in old, backward displacements, where the uterine appendages are destroyed by suppurative disease.

"DYSURIA IN WOMEN."

Dr. O. B. Will of Peoria, read a paper upon this subject. Acting upon the assumption of the zymotic origin of the trouble, his first thought was to neutralize the fermentative action taking place in the lower sections of the digestive tract. For this purpose he had used with great success charcoal and sulpho-carbolate of soda; the former administered in tablet form, five grains or more at a time, and frequently repeated; the latter in half dram or more doses, three times a day, before the taking of the respective meals.

As to the local treatment, years ago he used with success, in these cases of irritable bladder and urethra, a strong solution of nitrate of silver, injected into the organ, the resulting pain being held in abeyance by the use of large doses of morphia. Coupled with this forcible dilatation of the urethra for fissure came into vogue, and in some cases seemed to answer a good purpose. Wherever a state of tissue tension exists and free drainage is desirable, the stretching process is an admirable therapeutic adjunct, and is a preliminary measure to the treatment to which the author now resorts. The patient is placed in the elevated dorsal position, advised by Kelly, in exploring the bladder and catheterizing the ureters. After quickly mopping out the residual urine, if there is a hyperemic or analogous condition of the trigonal region, he applies at once, on the most dependent portion of that region, from a long-pointed syringe, a few drops of a ten or fifteen per cent. solution of potassa permanganate. Preliminary to this, however, he uses a ten per cent. solution of cocaine with which to dilate the urethra, a few drops of which introduced into the bladder serves to obtund in some measure the sensibility of its mucous lining. In cases where the whole tract from that point to the meatus is in an evident state of irritation, either with marked hyperemia or in an eruptive condition, he quickly swabs the pendent area of the bladder with cotton on a screw applicator, soaked in the permanganate solution, and, making sure that there is no sharp point to the applicator exposed, with it draw the charged cotton out through the distended urethra, following in the tract of the withdrawn speculum. After the application of the permanganate to the urethra it is generally advisable to introduce, within a few minutes a large sized bouge, heavily coated with lanolin, especially on the end, so that the lubricant may adhere more abundantly and extensively to the urethral wall. Even in those cases of dysuria associated with eczematous and urticaria-like eruptions in urethra and bladder, he had recently found this treatment to be most effective.

"ULCERATIVE INFLAMMATION OF THE CORNEA."

By Dr. E. O. Sisson of Keokuk, Ia. The author first dwelt upon the etiology, and then passed on to the subdivisions of keratitis suppurativa. Symptomatology and complications were next considered.

With regard to the treatment of corneal ulcers, the author reiterated the methods laid down in the several text-books.

"PYLORECTOMY IN AMERICA."

Dr. Alex. Hugh Ferguson of Chicago, in an interesting paper, said the literature up to date only shows thirteen resections of the pylorus in this country, and of this number eight died, and five recovered. The first successful pylorectomy performed in this country was by Dr. Wm. T. Bull of New York. The proportion of deaths immediately following the operation, places shock as the most prominent cause. In none of the cases reported is the nature of the shock stated, that is, whether it was manifested by marked cardiac inhibition, nervous depression, or excitement. The author then reported a case upon which he had successfully operated.

He is strongly in favor of encouraging pylorectomy for carcinoma of the pylorus, for the following reasons: (1) Medical treatment offers a mortality of one hundred per cent. within twelve or eighteen months. (2) Pylorectomy promises (*a*) a possible cure. In 19 per cent. of over nine hundred cases dying with cancer of the pylorus, no adhesions whatever were found after death; starvation took place before the carcinoma had reached the peritoneum. There would be good prospects of curing most of these. (*b*) Recovery from the operation in about 50 per cent. Death occurs in 43.7 per cent. while the disease is still local, *i.e.*, no secondary deposits, or extension beyond the pylorus. Surely some of these could be saved. (*c*) A still less mortality with early operation. By timely

interference many cases could be saved that now go on to secondary infection, and are doomed.

To secure the best possible results, shock must be anticipated and measures taken to prevent it. In addition to the hypodermic injection of strychnia, before the operation is commenced, the author is convinced, from a large experience in major work, that when the patient is placed on a hot water bed during the operation, that shock, which otherwise would have been pronounced, is in many cases altogether prevented. He feels certain that this precaution was a material contributing element to the success of his pylorectomy case.

After opening the abdomen, he recommends the performance of pylorectomy thus: (1) Liberate the duodenum from the pylorus, unite its distal cut end to the posterior surface of the stomach with Murphy's button, and invert the proximal cut end toward the pylorus and close with sutures. The great advantage of completing the gastroduodenostomy first, is that the operation can be safely stopped at this stage, should the patient show signs of weakening, the abdomen at once closed, and the removal of the pylorus left for a second operation. (2) Separate the stomach from the pylorus and close it rapidly with sutures. Should the patient now present alarming symptoms, the surgeon should again cease operating and leave the pylorus *in situ* in the meantime. It would, of course, be necessary to fasten it in the abdominal wound and drain it externally, which, however, would only facilitate its extirpation at another time. (3) Remove the cancerous pylorus. Spend no time in trying to use interlocking ligatures, but apply forcep after forcep and cut the mass away. This done, the application of ligatures can be executed more expeditiously.

"LOCAL TREATMENT OF THE EYE"

Was the title of a paper read by Dr. Dudley S. Reynolds of Louisville, in which he said that the local treatment of the eye was as much in need of reform and readjustment as in any other department of surgery, for there had been little change in prevailing customs for nearly a hundred years. It seems to him that it is rational for practitioners to get out of the nitrate of silver path of destruction and quit furnishing the aid of cauterization to the less destructive processes of a surface inflammation. Boric acid will protect abraded surfaces against the ordinary dangers of infection; cocaine will allay local irritation; and so these may be appropriately prescribed in every case of pain in the eye from foreign bodies. The yellow oxid of mercury he considers valuable as a local application in nearly all forms of ulceration or abrasion of the cornea and conjunctiva. The tension of the eyeball must be noted in every case of injury, and if found slightly increased, a solution of eserin should be instilled, a saline purgative administered, and if the increased tension be accompanied by sense of pain on pressure upon the globe, it is best to begin with salicylate of sodium or ammonium at once. Hot ablutions are often of great value in cases of irritation of the iris and ciliary body, whether due to constitutional or local causes. In cases of contusion, and in those cases of extravasation of blood from sneezing, lifting heavy bodies, and from various causes of rupture of small blood tubes, a solution of muriate of pilocarpin promotes rapid absorption of effused fluids. This may be instilled into the eye or injected under the retrotarsal conjunctiva in doses too small to perceptibly affect the heart.

DISCUSSION.

DR. FRANK ALLPORT of Minneapolis, thought that Dr. Reynolds had struck the keynote in certain phases of ophthalmic practise, in that he strenuously advocated the harmless treatment of the eye. He had seen so many instances of eyes that had been injured along the line indicated by Dr. Reynolds that the paper appealed to him very strongly. The longer he practises ophthalmology the more he feels the necessity of using mild and uninjurious remedies. He could not but believe that remedies, such as the doctor had indicated in his paper, that actually produced irritation of the conjunctival surface, or of the epithelium of the cornea, could be other than extremely injurious in cases of acute inflammation.

DR. WM. H. WILDER of Chicago, could not agree with the essayist, when he thinks that we should abolish the use of the stronger remedies in the treatment of diseases of the eye. They certainly have their use, and particularly in infectious cases, as gonorrhœal ophthalmia, whether in the newborn or in the adult. The severer cases of trachoma should be handled without gloves. It is true, their treatment requires skill, but there is no reason why the general practitioner should not familiarize himself with the methods necessary for the treatment of all of these cases.

"OBSERVATIONS ON SOME CRITICISMS OF SERO-THERAPY."

DR. PAUL PAQUIN of St. Louis, Mo., read this paper. No department of therapeutics has called forth so much criticism as sero-therapy. These criticisms have been of two kinds—those based on scientific problems of biology, and secondly, those based on clinical effects and results. The author considered these separately at length.

To show the most deleterious results of sero-therapy, injudiciously applied, the author had conducted experiments in animals and man, and analyzed the results. In a rabbit, in good health, the number of red blood corpuscles, per cubic millimeter, were 5,800,000. He injected 4 c.c. of pure horse-blood serum immunized, and three hours later the red blood corpuscles were counted again, and they had dropped to an average of 3,900,000 per c. m., a loss of 1,100,000 per c.m. of blood. Eight hours later, 3 c.c. more of pure blood serum of another horse was injected, and within four hours the red blood corpuscles had been reduced to practically 2,800,000 per c.m., or 3,000,000 less than before any injection. At the same time the leucocytes had increased in large numbers. Practically, the same results were obtained in a man, thirty-five years of age. The number of red blood corpuscles averaged 4,400,000 per c.m., before injecting pure horse-blood serum. Ten c.c. were injected in one dose, the patient never having received it before. Four hours later the red blood corpuscles averaged 3,800,000 per c.c. Six hours later they averaged 3,000,000. Again, in this instance, the white cells were enormously in

creased. In the experiments, both in man and animal, in which the blood cells were diminished largely in number, the temperature declined slowly below normal, and there were pronounced symptoms of depression.

A phase of criticism is based on the idea that in using serum, some fatal, or at least dangerous animal diseases, such as glanders and tuberculosis, may be transmitted to man. This is well founded. Glanders has thus been transmitted, if we are to believe the reports of the press, but this danger can be easily avoided. As to the beneficial effects of serum, these depend unquestionably, in a great measure, upon increased phagocytosis. The serum increases the white cells, whose duty it is in part to destroy micro-organisms in tissues and their toxins, probably by a process of cellular digestion, or rather a diastatic neutralization. In a tuberculous man of thirty-five years, in which the white cells were less than 16,500 per c.m., they were increated to over 40,000 in seventeen days by the daily injection of 2 c.c. of antitubercle serum. The author obtained a similar result in a rabbit, in which he had injected Roux antitubercle serum daily for three days, the dose being 1 c.c.; also with other serums in other small animals.

"THE RELATIONS WHICH SHOULD EXIST BETWEEN OCULISTS AND OPTICIANS."

By Dr. Frank Allport of Minneapolis. He advanced strong arguments in favor of licensing opticians to fit glasses. The fitting of glasses was not a trivial affair, but necessitated, in many instances, a thorough examination of the eyes by a properly equipped, specially trained, medical practitioner.

DISCUSSION.

Dr. Dudley S. Reynolds of Louisville, said it frequently happens that a neurotic person consults the ophthalmic surgeon with two or three, or perhaps half a dozen pairs of spectacles in his possession, and on suspending the accommodating power of the eye and testing the state of refraction no glasses are needed.

Dr. Ryan of Galesburg, said that every practitioner, who is doing more or less ophthalmic work, had seen evidences of the injury done by traveling opticians and spectacle venders. Every general practitioner should look at the eye, not as a machine, but as an organ which performs a general physiological function.

Dr. R. Harvey Reed of Columbus, O., said that legal measures would soon be enacted in Ohio to prevent the optician from encroaching upon the field of the ophthalmologist. The instrument makers would also be included if the bill should become a law.

The subject was further discussed by Drs. Wilder and Hale of Chicago, and Dr. Ball of St. Louis.

"THE OPERATIVE TREATMENT OF JACKSONIAN AND FOCAL EPILEPSY, AS ILLUSTRATED BY SELECTED CASES."

Dr. Chas. B. Nancrede of Ann Arbor, Mich., read this paper. The cases reported by the author demonstrated what has been the experience of Horsley, Keen, and other surgeons, namely, lack of permanency in results. The great difficulty is a reliable method of preventing adhesions. The removal of the lesion in cortical and Jacksonian epilepsy can only be regarded as palliative. The earlier the operation is done after the disease has become established, the longer the immunity. It is possible that if trephining is resorted early, the operation, in a few instances, might prove curative, if a reliable method is devised to lessen the inevitable scar and to prevent adhesions between the membranes and brain, Operation is not dangerous in competent hands, especially when performed early.

"SOME NEEDED REFORMS IN MEDICINE."

This was a public address delivered (by invitation) by Dr. Joseph M. Mathews of Louisville, Ky. He first dealt with specialism, according all honor to the specialist. Professors in medical colleges should educate students that the great object in medicine is to practise it; and yet we find blooming into special lines of work every day all over the Union, both in the city and country; young men, without any special preparation either for surgery or for any other particular line of medical work, setting themselves up as learned men in special departments. The profession should call a halt. It should be impressed upon the minds of students that thorough preparation is necessary in order to be a specialist, and unless this is done, specialism would be brought into disrepute. No man can be a specialist in any department who has not fitted himself and had experience in the general line of practise. Reform was needed in the appointment of medical men to fill places in medical institutions, such as asylums, etc. Too often petitions were circulated and signed in favor of this and that man, without taking into consideration professional qualifications.

EXPERT TESTIMONY

Should be raised to a higher plane, and those who testify as experts should receive adequate compensation therefor.

ATTENDANCE AT MEDICAL SOCIETIES.

In the State of Kentucky there are four thousand registered practising physicians. Of this number, about four hundred belong to the State Medical Society. Dr. Mathews believes that this small membership obtained proportionately in other States. The live, busy, energetic, and most eminent practitioners attended medical societies.

CONSULTATIONS.

The old rule that applied to consultations does not hold good to-day. Specialism was not known until recent times. There has been a change in the order of things, and practitioners of medicine have to meet the issue just as it is. To-day a patient either belongs to the physician or to the specialist, and not to both alike. When a specialist recognizes that a patient does not require his special attention, he should call a physician. Per contra, when a physician recognizes that a patient needs special attention, he should give the patient to the specialist.

Dr. Mathews then strongly condemned the endorsement by medical men of preparations, the compositions of which they know comparatively nothing. A reform was absolutely indispensable in this regard.

CODE OF ETHICS.

This document needed no defence from him, as it

stands open to the world. He did not believe there was a man or woman in the profession who could raise any objections to what is taught therein. The perfect gentleman, however, in his professional relations could control his actions without the code, and act with honesty toward his fellowmen, at the same time there is nothing in the code to which honorable men could object.

QUACKS.

The State Board of Health of Kentucky had succeeded in driving out of the State within the last two years over 860 charlatans. How was this accomplished? By the concerted action of the medical profession and the representatives in the State Legislature.

Dr. Mathews then paid an eloquent tribute to the good work that had been done by the Illinois State Board of Health.

DR. R. HARVEY REED of Columbus, contributed a paper entitled

"SOME PRACTICAL REASONS FOR EARLY OPERATION IN APPENDICITIS."

(*To appear shortly in the* MEDICAL NEWS).

DR. GUSTAV FUETTERER of Chicago, described a new method of treating gonorrhœal infections of the knee-joint, in which he had successfully used injections of oil of sandalwood. He employs the best preparation of this kind made.

CLINICS.

A clinic was given at the Post-Graduate Medical School by Dr. J. B. Murphy before the members of the society. Dr. Murphy did a cholecystotomy in one sitting.

At Rush Medical College clinics were given by Dr. J. H. Etheridge and Dr. Fernand Henrotin. Dr. Etheridge did a laparotomy for hydrosalpinx on one side and pyosalpinx on the other, while Dr. Henrotin performed a vaginal hysterectomy for malignant disease.

Dr. Nicholas Senn, at his usual Thursday afternoon clinic in Rush Medical College, exhibited several patients upon whom he had previously operated for peritoneal tuberculosis, these cases beautifully illustrating the varieties of this affection. He next showed and expatiated upon the following cases upon which he had operated: Tubercular appendicitis, tubercular perichondritis, several cases of tuberculosis of the cervical glands, sarcoma of the breast, tubercular synovitis of the knee-joint; pyloric stenosis, pseudo-leukemia, a case of hernia operated on by the Bassini method; tubercular osteomyelitis implicating the phalanges of the toes; penetrating gunshot wound of the knee-joint, etc., etc.

The following officers were elected for the ensuing year:

President—Dr. A. H. Cordier, Kansas City, Mo.

First Vice-President—Dr. Hugh T. Patrick, Chicago, Ill.

Second Vice-President—Dr. H. C. Eschbach, Albia, Ia.

Secretary—Dr. Geo. W. Cale, St. Louis, Mo.

Treasurer—Dr. C. S. Chase, Waterloo, Ia.

St. Louis was selected as the place of the next meeting.

OBITUARY.

DR. JOHN F. MCKENZIE died at Leroy, Ill., April 13th, of a cancerous affection of the bowels. He was fifty-three years old. He was a native of Kentucky, a cousin of Vice-President Adlai E. Stevenson, and brother of James McKenzie, Minister to Peru. Dr. McKenzie was superintendent of the asylum for the insane at Jacksonville, Ill.

ON the 16th instant Dr. A. L. Williams of Brookfield, Conn., was struck and killed by a train. Dr. Williams was the oldest practising physician in his State, and had continuously practised in Brookfield for sixty years.

DR. WILLIAM SHARP died in Wales two weeks ago. Dr. Sharp was an original investigator, and it was owing to his influence that physical training was introduced in the public schools of England. He began the study of medicine in Guy's and St. Thomas' hospitals in 1825, under Sir Ashley Cooper.

DR. JOHN J. DALY of Rahway, N. J., died on April 14th. Besides acquiring a high degree of success and an enviable reputation in his profession, Dr. Daly had acted as a reform mayor of his city during five terms.

DR. WM. HUNT, for many years a well-known, able, and conservative surgeon, died at his home in Philadelphia on April 17th, after a somewhat protracted illness. He never entirely recovered from the effects of injuries received in being struck by a wagon some time ago. Dr. Hunt was born in Philadelphia on September 22, 1825, and at the age of twenty-one years entered the medical department of the University of Pennsylvania as a pupil of the late Dr. George B. Wood, and graduated in 1849. He was elected resident physician in the Pennsylvania Hospital in 1850, and in 1854 became Demonstrator of Anatomy in the University of Pennsylvania, continuing in this last position for ten years. In 1856 he was elected surgeon to the Episcopal Hospital and served in that capacity for more than twelve years. In 1863 he was elected surgeon to the Pennsylvania Hospital and held that position until 1893, when, in accepting his resignation, the Board of Directors adopted a resolution expressive of their appreciation of his services during the period of his more than forty-three years' continued connection with the hospital. Dr. Hunt was also, at different times, surgeon to the Orthopedic Hospital and to Wills Eye Hospital. During the Civil War he served as an acting assistant surgeon in the United States Army. He was a trustee of the University of Pennsylvania, a Fellow of the College of Physicians of Philadelphia, a member of the Philadelphia County Medical Society, and of the Philadelphia Academy of Natural Sciences, ex-President of the Philadelphia Academy of Surgery, and Honorary Fellow of the American Surgical Association. During the active period of his career Dr. Hunt made a number of valuable contributions to medical literature. He was joint author of an elaborate paper descriptive of "Surgery in the Pennsylvania Hospital: Being an Epitome of the Hospital since 1856."

ORIGINAL ARTICLES.

REPORT OF A CASE OF INDIGENOUS PARASITIC CHYLURIA WITH FILARIA NOCTURNA IN THE BLOOD.[1]

BY FREDERICK P. HENRY, M.D.,
OF PHILADELPHIA;
PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE IN THE WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA.

Fanny B., married, aged twenty-nine, was born in Columbia, S. C., and spent the first twenty-seven years of her life in that town. Her twenty-eighth year was passed in Palatka, Fla., and her twenty-ninth in Philadelphia, where she arrived in March, 1895. Her father died from sunstroke, and her mother, for several years before her death, suffered from "shingles"—herpes circinnatus.

She had the usual diseases of childhood, except scarlatina. At the age of twelve she fell from a fig-tree, and soon after developed a large abscess in the left lumbar region, the site of which is plainly indicated by a cicatrix about three inches long, a little above and parallel with the posterior portion of the crest of the ilium. This abscess continued open for several months, but finally healed. A year after its closure another abscess appeared in the left iliac region, and also pursued a chronic course. Its site is indicated by a linear cicatrix, about two inches long, a little above and parallel with Poupart's ligament. The patient suffered from what she vaguely described as an attack of malarial fever in March, 1895, but never manifested any signs of malarial infection while in the South. She has had two miscarriages: one at four months and a half; the other at two months. Both were ascribed to persistent vomiting. Three weeks before her admission to the Woman's Hospital of Philadelphia—she was admitted on February 16, 1896—she gave birth to a child at term. The labor was natural in all respects. Previous to the birth of her child she suffered from pain in the region of the kidneys. On the second day of her lying-in this pain became intense and continued for a week, when it abated somewhat. On admission it was still complained of. On the third day of her lying-in she passed milky urine, and had difficulty in micturition on account of the occlusion of the urethra with what she regarded as stringy masses of mucus. There were, in reality, coagula of lymph and blood. The urine, after standing for several hours in a narrow, cylindrical vessel, separates into two portions, of which the lower is distinctly hemorrhagic; while the upper, has the appearance of milk or cream. Floating on the upper chylous layer are numerous coagula of a delicate, pinkish hue, and almost translucent, while at the the bottom, are a few small blood clots. A little of the urine was shaken up in a test tube with ether and set aside until the urine and ether had separated. The latter being then evaported on a watch-glass, a distinct deposit of fat was obtained. The chylous urine contained a trace of albumin, but no sugar, and was free from casts.

I found this woman awaiting me at my clinic at the Woman's Hospital on Tuesday, February 18, 1896, and lectured upon her case as one of chyluria, probably parasitic. On the evening of February 19th I visited the hospital for the purpose of examining my patient's blood for the filaria sanguinis, taking with me a small microscope and making the search with a half-inch objective. I withdrew the blood from the finger about 10 P.M., and examined several slides without finding the parasite. I left the slides at the hospital, and after my departure one of the resident physicians, Dr. Ida E. Blackburn, examined them with a stronger lens, and fortunately succeeded in detecting the filaria. Since then filariæ have been found in almost every slide examined. They are not numerous, the maximum number observed on a single slide being five. The urine was repeatedly examined, the centrifugal machine being used to separate the parasites, but only on one occasion were they found in that fluid. With the specimen in which they were detected the centrifugal machine was not employed. The filariæ have not been found in the milk of the mother or in the blood of the infant, and they are very few in number or absent from the blood of the mother during the day. The variety present in this case is, therefore, the filaria nocturna, the embryo of an adult which is alive in one of the lymphatic channels.

The patient was put to bed, and frequent examinations were made of her blood and urine. She was at first placed upon quinin and ergotin, without any apparent effect, the urine continuing chylous and bloody, although in an intermittent manner. February 25th, I examined the blood, and found filariæ. I then directed leeches to be applied to the lumbar region, ostensibly to relieve pain, but in reality to test the question whether the leech might play the rôle of an intermediate host to the filariæ. Three of the leeches were sent to me the next morning. I opened one of the leeches at 10 A.M., and examined its blood. Filariæ were abundantly present—one slide contained six—and actively moving. The next morning (February 26th) they were still active. The same afternoon I found three dead filariæ on one

[1] Read at the meeting of the Association of American Physicians, at Washington, D. C., May 1, 1896.

of the slides, and but one still living and languidly moving. At the same hour the filariæ removed directly from the body were all living. On February 29th I opened another leech, and found a number of dead filariæ in its blood—none living. It appears evident, therefore, that although the filariæ may live many hours in the body of the leech, that animal does not play the part of an intermediary host to them.

February 28th, the patient was placed upon thymol (gr. ii. every three hours), and coincidently with its administration, the urine became normal in every respect, and so continued for seven days, when it again became chylous and bloody. The filariæ during this interval were abundantly present in the blood.

March 12th, I ordered methylene blue in two grain capsules every three hours, being induced to do so by the remarkable statements of Dr. Austin Flint, concerning the efficacy of this substance in a case of parasitic chyluria.[1]

March 13th, I found Mrs. B. out of bed and dressed. Her appearance was good, her lips and cheeks being well-colored; urine deep blue; eye-ground examined by Dr. Gertrude A. Walker, ophthalmologist to the hospital, who confirmed my observation as to the abscence of any morbid appearance in the retina. Patient anxious to go home, but persuaded to stay another week.

On Saturday evening, March 14th, I obtained some blood from the finger as usual, and examined it the next morning. I had scarcely placed the first slide under the microscope when I detected two filariæ (in the same field) moving with the greatest activity. I was unable to perceive that the filariæ were stained in the slightest degree by the methylene blue which the patient, at the time the blood was withdrawn, had been taking continuously for seventy-two hours. Her urine and feces were stained a deep blue, but *the milk was uncolored.* Thus far I find no corroboration of Flint's statement that methylene blue stains the filariæ in the circulating blood, much less that it exerts any deleterious influence upon them. My experience, although differing from that of Flint, in this matter, is precisely in accord with that of Laveran,[2] who found that the filaria perished a few seconds after it was brought into contact with a drop of a solution of quinin, of the strength of 1–1000, while methylene blue (strength of solution not stated) does not hasten their death, and does not stain them until they are dead.

March 17th, Mrs. B. came downstairs to my clinic at the Woman's Hospital; specimen of her urine, deeply stained with methylene blue, exhibited. Blood was withdrawn from her finger at one o'clock, and seven slides prepared. These were repeatedly examined by myself and an assistant, the result being that two filariæ were found in the seven slides. This is the third time in which the blood has been examined by day, namely, once before at one o'clock, when no filariæ were found, and once at 8 A.M., when only one was discovered. It is evident that the parasites are much less numerous in the superficial capillaries by day than by night. This is the sixth day since the treatment with methylene blue was instituted, and the results, thus far, are by no means encouraging. The drug appears to be absolutely inert, so far as concerns the destruction of the filariæ. Different opinions as to whether or not the filariæ were stained, were expressed by those who saw the specimens. The majority thought they were not, but being on the lookout for such staining, I *fancied* that they had a faint bluish tinge.

March 19th, at one o'clock, the patient having been taking methylene blue (two grains every three hours) for one week, I counted the blood corpuscles. Number of red corpuscles per cubic millimeter, 4,100,000; white not increased in number and *unstained.* Hemoglobin, sixty-five per cent.

Five slides of rapidly dried blood were prepared, and no filariæ found. It is a singular fact that the previous day, while the patient was taking the methylene blue as usual, the urine suddenly became quite clear and macroscopically normal.

I gave two slides of blood to Dr. Alfred Stengel, of the Pepper Laboratory of Clinical Medicine (University of Pennsylvania), in order to obtain his opinion as to whether or not the leucocytes were stained with the methylene blue, which the patient had been taking continuously in full doses for more than one week at the time the blood was withdrawn. Dr. Stengel reported that he could find no evidence of blue discoloration of the corpuscles.

March 20th, at nine o'clock in the evening, I prepared a number of slides. The filariæ were abundantly present. I found them in eighteen out of twenty-one preparations, and, as I did not use a mechanical stage, it is possible that I may have overlooked them in the three slides, in which the search was ineffectual. The serum of the blood was decidedly blue, and the filariæ of an exceedingly delicate bluish tinge. The methylene blue had been taken by the patient continuously in full doses for nine days and had proved absolutely inert, so far as any influence upon the vitality of the embryos is concerned.

March 21st, the patient returned to her home.

I omitted to state that shortly after the patient's admission I had her vaccinated on the theory that an intercurrent infection might destroy the parasite. The vaccination was perfectly successful, but quite as useless from a therapeutic standpoint as the methylene blue.

The above case is of special interest both because it is the first of the kind observed in Philadelphia, and also for the reason that it adds another to the list of those indigenous to the United

[1] *New York Medical Journal*, June 15, 1895.

States. It is impossible to say how long the filarial embryos have been circulating in the blood of this patient, but it is in the highest degree probable that the infection occurred either in South Carolina or Florida, and it is not impossible that the lumbar and inguinal abscesses, from which she suffered at the age of twelve, were due to the filariæ. Similar abscesses form part of the clinical history of filariasis. The exciting cause of the chyluria was probably the rupture of a dilated lymphatic during the expulsive pains of labor. The supposition that infection occurred at the age of twelve or earlier necessarily implies the circulation of the embryos in the blood for many years without giving rise to symptoms. In connection with this question of the innocuous presence of the filariæ in the blood of men the following case is of interest:

In the autumn of 1893, a well-known physician of Philadelphia consulted me about his son-in-law, who had resided for some years in Columbia, S. C., and latterly near Tampa, Fla. Filariæ were said to have been found in his blood by de Saussure of Charleston. Up to the time I speak of the symptoms had been those of intestinal indigestion, consisting chiefly of great abdominal distress, meteorism, irregular action of the bowels, great nervous excitement at times, *especially toward evening*. I examined the patient's blood in vain for the filariæ, and Professor Guiteras, who examined it twice, was equally unsuccessful. The time of my examination was about 10 P.M., and I have since thought that my failure to detect the parasite may have been due to the fact that the patient walked to my office. The gentleman in question returned to his home in Florida, and a few months later passed chylous urine for the first time. The chyluria continued for one or two months, and has not returned. Of late the patient has been in a fair state of health, and free from the intestinal symptoms above-mentioned.

Post-mortem examination, of those who have perished from parasitic chyluria, has revealed enormous distention of the lymphatic vessels of the urinary tract, and sometimes also of the thoracic duct. A few months ago, I exhibited before the Philadelphia County Medical Society a specimen of chyluria from a Cuban, whose blood I vainly searched for the filaria. I had but one opportunity of examining the blood of this man, and for that I was indebted to Dr. Charles W. Coburn, who was in attendance upon the case. Shortly after my examination the man died and an autopsy was held under very unpropitious circumstances. There was, however, no difficulty in ascertaining that the lymphatic vessels, especially those of both renal regions, were enormously dilated and convoluted, many of them being of the caliber of an ordinary lead pencil. The dilatation was most marked on the right side, and in the pelvis of the corresponding kidney there was a pale lymph clot similar to the coagula passed with the urine during life. In this case it is greatly to be regretted that a careful dissection with a view to the detection of one or more of the adult filariæ was not possible. The time at our disposal was limited, and the light was derived from a single lamp which was held by turns by Dr. Coburn and myself, the autopsy being skilfully performed by Dr. Bundy of the Woman's Medical College of Pennsylvania.

The importation of a case of filariasis into a city of the latitude of Philadelphia naturally raises the question whether the disease may become endemic therein, and there seems to be no good reason why it should not. The brilliant researches of Dr. Patrick Manson have established the fact that the mosquito plays the part of an intermediary host in conveying the *filaria nocturna* from man to man. At night the embryos swarm to the surface, while during the day they retire to the deeper vessels. Acting upon this knowledge, Manson exposed a filaria patient to the bites of mosquitos, and found the embryos in the bodies of these insects, in which, in the course of from five to seven days, they attain a length of one-fifteenth of an inch. In the blood of man, they measure from $\frac{1}{70}$ to $\frac{1}{80}$ of an inch, and are enclosed in a sheath, from which they make their escape in the viscid blood of the mosquito. The mosquitos with the embryonic filariæ in their interior seek water in which to deposit their eggs. This function accomplished, they perish; the embryonic filariæ are liberated, and, through the medium of the water in which they exist, gain access to the human system. One or more of the ingested parasites attains maturity in the lymphatic system and continues for an indefinite period (in some cases for many years) to produce swarms of embryos. The latter being but $\frac{1}{3500}$ of an inch in diameter, readily traverse the lymphatic glands, and reach the blood vessels via the thoracic duct. It is through the plugging of the lymphatic vessels, especially those connected with the urinary tract, that the lymph and chyle become mingled with the urine. For further details concerning the life history of this parasite, and the mode in which it occludes the lymph channels, the reader is referred to the writings of Manson.[1]

[1] Especially the articles in Davidson's "Hygiene and Diseases of Warm Climates"; *International Clinics*, April, 1895; "Transactions of the International Congress of Hygiene and Demography," Seventh Congress, 1891.

In Philadelphia, mosquitos are abundantly present during the summer and autumn, and have convenient access to the Schuylkill River, from which our water supply is derived. The chance of a given individual becoming infected through the medium of a river of the volume of the Schuylkill is doubtless infinitesimal, but no one acquainted with the wonderful vitality of the embryonic filaria can deny its possibility. The surest safeguard against this and other sources of infection is filtration.

The *filaria nocturna* is now known to be indigenous in Europe, as appears from the report of a case recently studied by M. Font of Spain.[2] The patient was a man, thirty-five years of age, who had resided all his life at Canet de Mar, with the exception of a short period passed at San Sebastian and Vitoria. Canet de Mar is a town of 5000 inhabitants on the shore of the Mediterranean, in latitude 41° 37′ north, between Barcelona and the French frontier, and is a favorite retreat for veteran sailors, many of whom have visited the West India Islands. Dr. Ballester, in a communication to Font, reports having seen in the same town two cases of hematochyluria during fourteen years, in neither of which was there an examination of the blood. In Font's case the presence of the *filaria nocturna* was repeatedly demonstrated.

Thus far three species of filaria have been certainly detected: (1) *Filaria diurna*, (2) *Filaria nocturna*, (3) *Filaria perstans*. These names are indicative of the habits of the animal, the *filaria diurna* being found in the superficial vessels solely or chiefly during the day; the *filaria nocturna* solely or chiefly during the night; while the *filaria perstans* is constantly present in the capillaries of the integument. The *filaria diurna* and the *filaria perstans* are confined, thus far, to the west coast of Africa and adjoining districts; while the *filaria nocturna* is pandemic in the tropics and endemic in certain sections of the United States. The adults of *filaria nocturna* have been frequently found; that of *filaria perstans* never, so far as I have been able to ascertain. In the opinion of Manson, the *filaria loa* of the eye of the negro of Old Calabar is probably the adult form of the *filaria diurna*. If it is not, he argues, then there must be another blood worm yet to be discovered, for the embryos of the *loa* must escape from the body of their host through the medium of the circulation. The *filaria perstans* has been practically proved by Manson to be the cause of the fatal "sleeping sickness" of the Congo region.

While engaged in writing this article my attention was called by Dr. Charles A. Oliver of Philadelphia, to a remarkable case of *filaria loa*, recently reported by Dr. Argyll Robertson. The patient was a lady who had spent eight years in missionary work at Old Calabar on the West coast of Africa. Without entering into the details of this interesting case I will merely state that in two successive operations Dr. Robertson extracted two *filariæ* (variety *loa*) from the ocular tissues, the first a male, the second a female. Both of these adult parasites are described by Manson in the course of Robinson's paper. The female was stuffed with embryos, but repeated examinations of the blood failed to detect any embryonic filariæ in that fluid. The latter fact certainly seems to refute Dr. Manson's hypothesis that the *filaria loa* is the adult form of the embryonic *filaria diurna*.

In a letter recently received from Dr. Manson, he says that America possesses the

> "unenviable distinction of possessing a filaria of the blood, which is possibly peculiar to itself. I found it in negroes from the island of St. Vincent, and I have little doubt but that it could be found in the negroes of the more tropical States of the Union. This filaria I have named *Filaria Demarquayi*, after Demarquay, the discoverer of *filaria nocturna*. It is a very small worm, not half the size of the filaria you are familiar with. It observes no periodicity; it is sharp-tailed, and it possesses a sheath," etc.

This *Filaria Demarquayi*[1] should, therefore, be added to the list above given, so that, at the present time, there are four distinct varieties of *filaria sanguinis hominis*.

The steps by which our present knowledge of the *filaria nocturna* has been obtained were gradual. The embryo was first discovered by Demarquay in 1863 in the liquid of a chylous hydrocele; next, in the blood by T. R. Lewis of India, in 1872. In 1876, the adult parasite was found in a lymphatic abscess of the arm by Bancroft of Brisbane, Australia, and is accordingly, known to helminthologists as the *filaria Bancrofti*, this name having been assigned to it by Cobbold. Finally, our knowledge of the life history of the parasite has been completed by the genius of Manson. We are irresistibly reminded of the analogous history of the discovery of trichiniasis, with which the names of Hilton, Paget, Owen, Leidy, and Zenker are associated.

In the United States filariasis can no longer be

[2] *Revista de Ciencias Medicas de Barcelona*, 25 February, 10 Marzo, 1894.

[1] I would suggest that the last-mentioned parasite would be much more appropriately called *filaria Mansoni*.

considered as an extremely rare disease, and it is probable that it is more prevalent in certain of our Southern States than is suspected. Professor John Guiteras, of the University of Pennsylvania, was the first to demonstrate the existence of endemic parasitic chyluria in this country,[1] and de Saussure[2] of Charleston, has published the clinical histories of twenty-two cases of filariasis observed in Charleston, S. C., from 1886 to 1890. Two cases of filariasis indigenous to Virginia have been reported by Dr. R. M. Slaughter,[3] but in neither of them was the blood examined. In both there was hematochyluria and filariæ in the urine, and in one filariæ were found in the pus of an alveolar abscess. While I believe these cases of Dr. Slaughter to be genuine examples of filariasis, I cannot refrain from the criticism that the illustration accompanying his paper bears but a superficial resemblance to the embryonic *filaria nocturna*.

Another indigenous case is reported by Dr. C. W. Mastin of Mobile, Ala.,[4] the patient being a young man, age twenty-two, who had never been outside of Mobile and its immediate vicinity. In Mastin's case the filarious lesion was a chylous hydrocele. The filaria is also said to be have been found by Weiss in the urine of a child who had never been out of Illinois.[5] I am by no means sure that I have collected all the reported cases of indigenous filariasis; in fact, I have made no attempt to do so. Sufficient, however, has been said to show that the disease is widespread and not confined to tropical and sub-tropical regions.

In this connection I may remark that the embryonic *filaria nocturna* is capable of great resistance to cold. My slides, prepared in winter and kept in a cold room, showed the parasites active at the end of six or seven days; in fact, one lived for ten days. Exposure for many hours to a freezing temperature does not kill them, as proved by one of the methods employed by Manson to demonstrate "filarial ecdysis." This consists in placing the slide containing the filariæ upon a block of ice overnight, in order to cause a separation of hemoglobin from the red corpuscles. The effect of this degree of cold is to render the movements of the animal somewhat languid, but after withdrawal from the ice they become as active as before, and the embryos speedily escape from their sheaths.

Facts such as the above seem to prove that nothing but time is needed for filariasis, the scourge of certain tropical countries, to become prevalent in our own, and demonstrate the vital importance of municipal filtration of our water supply.

I have said little about treatment in the foregoing remarks because I do not believe there is any drug capable of destroying adult filariæ in the human system. Surgeon-major E. Laurie of Hyderabad, reports two cases which he believed to have been promptly cured by thymol,[1] the maximum dose being five grains twice daily. Walsh, of the general hospital of Calcutta, also reports success from the use of thymol. On the other hand, Crombie, of the same institution, has given two hundred grains of thymol daily in one case, and forty-five grains daily in another, without producing any effect upon the worms. As the latter justly remarks, "thymol is so exceedingly insoluble that it is improbable that any appreciable quantity of it left the intestinal canal."[2]

I consider it a very fortunate circumstance that the case of Fanny B. came under my observation at a time when I was able to secure the co-operation of such an expert in photomicrography as Dr. Charles Lester Leonard, whose arduous work has been pursued in the Laboratory of Hygiene of the University of Pennsylvania. The appended illustrations are all *photographs of the living parasite*, and this is, I believe, the first time in which the living filaria have been photographed under a one-twelfth oil immersion lens, or, so far as I am aware, under any. The representations are, therefore, absolutely accurate, and necessarily take precedence of any drawings of the living or photographs of the dead nematode. To show the fallacy of drawings, I may say that one artist pictured the worm with long cilia waving from its head, while another was unable to see anything of the sort in the same specimen. I may say, in this connection, that I am inclined to believe in the existence of such cilia, although they are not shown in the photographs; unless they are indicated by the blur in Fig. 5. The point I wish to emphasize is that nothing can be represented in the photographs that was not present at the time they were taken.

I may say also that I have been unable to detect the "cephalic armature" described by Manson, although the "pouting" movement of the head was plainly visible. In mentioning my inability to detect the cephalic spine, or fang, I have no intention to impugn the accuracy of

[1] *Lancet*, February 14, 1891.
[2] *Lancet*, August 13, 1892.

Manson's description. I attribute my failure entirely to my deficient training in this line of research.

In conclusion, I wish to express my thanks to Dr. Anna M. Fullerton, the distinguished physician in charge of the Woman's Hospital of Philadelphia, and to her assistants, Drs. Blackburn and Carpenter, for their kind and skilful co-operation with me in my study of this interesting case.

Postscript.—I visited Fannie B. at her home on March 25th, and found her in good condition. she informed me that since leaving the hospital, her baby's feces have been stained blue. She is taking ten grains of methylene blue daily—two grains every three hours.

March 28th, patient's milk now faintly stained blue. Treatment continued,

March 29th, visited the patient this evening and prepared eleven slides, in every one of which I found filariæ in most active movement. She has now been taking methylene blue since March 12th. From the 12th until the 21st, the dose was two grains every three hours—sixteen grains per diem—and from the 21st until the 29th, it has been ten grains a day, in divided doses of two grains. The drug, in this case, has proved absolutely inert. The patient's urine is deeply stained, and her milk very slightly stained. The baby's fecal discharges are blue, and his urine also of a faint bluish tint. Filariæ of a very faint bluish tinge. Leucocytes unstained. A few filaments of cotton on the different slides were stained of a faint bluish tint by the blood plasma with which they were in contact.

From the above it is manifested that my experience with methylene blue in parasitic chyluria is entirely different from that of Austin Flint and Joseph N. Henry.[1]

The latter in his report to Flint says:

"The effects of methylene blue in this case were decided and prompt. After the administration of two grains every two hours during the day on March 5th, the parasites were very few at 11 P.M.; the only two found were deeply stained with blue, and their movements were extremely sluggish, the urine being clear but intensely blue. On the fourth and seventh days no parasites were found, although the treatment had been discontinued after the first day. On the eighth day, the urine became milky, and on the night of the ninth day, filariæ were found in great number, but their movements were not very active. On the tenth day, the treatment was resumed, and continued for five days. Three days after, the blood being examined at night, a very few motionless filariæ were observed. Since that time and up to the present writing, the urine has been normal and the patient has been restored to perfect health."

Admitting the disappearance of the parasites in Joseph N. Henry's case, I believe it to have been a mere coincidence and in no way related to the administration of methylene blue. I have given this drug in larger doses than were used in the case reported by Flint, and for a much longer period, without the slightest effect upon the parasite.

Explanation of the Accompanying Plate.

Fig. 1.

The movement of a single filaria during a series of four successive instantaneous exposures. The length of each exposure was one-fifth of a second, the entire series occupying less than five seconds. The magnification is to eight hundred diameters, with a Zeiss one-twelfth homogeneous immersion lens.

Fig. 2.

Filaria alive in the blood. Instantaneous photomicrograph. Four hundred diameters magnification. Four millimeters Zeiss apochromatic.

Fig. 3.

The same as Fig. 2. Magnified to fifteen hundred diameters. Showing structure and commencing granular degeneration.

Fig. 4.

Tail of filaria showing sheath extending beyond the apparent end of the tail. Eight hundred diameters.

Fig. 5.

Head of living filaria. The blur in front of the head is probably due to the motion of cilia. Fifteen hundred diameters.

Fig. 6.

Shows the head of a filaria overlapping a red corpuscle. The appearance might readily be mistaken for the cephalic end of a sheath. Magnified eight hundred diameters.

THE USE OF THYROID EXTRACT IN CONDITIONS OF LOWERED VITALITY OTHER THAN CRETINISM AND MYXEDEMA.

By HENRY M. FISHER, M.D.,
of Philadelphia.

The very remarkable results obtained by Professor Schiff and Dr. Van Eiselsberg by implantation of portions of the thyroid gland in the bodies of animals upon which thyroidectomy had been performed, inspired Mr. Victor Horsley[1] with the idea that myxedema in man could also be so treated.

The suggestion made by Mr. Horsley was acted on by Lannelongue in Paris and Bettencourt and Serrano[2] in Lisbon, who undertook the actual implantation of the sheep's thyroid beneath the skin of the human subject for the relief of myxedema.

Later injections of fresh thyroid juice were practised with success for the relief of the above disease by Messrs. George R. Murray[3] and Hurry Fenwick.[4]

Feeding with fresh sheep's thyroid glands was found by Dr. Hector W. G. Mackenzie[5] to give equally good results and finally various preparations, liquid and solid, of an extract of the fresh sheep's thyroid have been used.

Having observed desquamation of the skin, especially on "the palms of the hands and soles of the feet" resulting from the administration of thyroid juice "in all cases of myxedema and sparodic cretinism, in which he had the opportunity of carefully following the effects of the treatment;" Dr. Byrom Bramwell[1] decided to try thyroid feeding in the treatment of psoriasis, and, in three cases (one of six and a half years' duration) the treatment was entirely successful.

Since that time many practitioners have tried the remedy for psoriasis and other forms of skin disease and also in secondary syphilis.

Dr. J. Duncan Menzies[2] reported marked improvement after the administration of thyroid extract in four cases of "malignant Indian syphilis," which had been slightly, if at all benefited by the usual anti-specific remedies. Dr. P. S. Abraham, at a meeting of the Hunterian Society of London, in 1894, presented a case of lupus, which had been greatly benefited by the treatment. The same observer reported at a meeting of the Medical Society of London the effects of thyroid feeding on sixty-five cases of psoriasis. In only eighteen of these cases, however, was there marked improvement; in fifteen there was an actual increase in the eruption, and in twenty-eight "headaches, palpitations, tremors, neuralgic pains, dyspeptic symptoms, in short the various manifestations" of "thyroidism" were so soon complained of that the treatment had to be discontinued. He concludes that the treatment "has no constant effect in psoriasis." Numerous other observers have reported either negative or positively unfavorable results from the injection of the thyroid gland, or its extract, in cases of psoriasis.

The following single case appeared to me of sufficient interest to put on record, from its confirming the already published reports of the marked effect sometimes observed in the nutrition of the skin, in consequence of thyroid feeding. It will be observed that while the results obtained might at first have been attributed to the local measures adopted, in conjunction with the injection of the thyroid extract, the equally favorable result observed later, when no local treatment was used is evidence that the cure was largely due to the thyroid feeding.

Mrs. Mary F., aged forty-seven, consulted me March 6, 1895, on account of an ulcer in the sole of the right foot, from which she had suffered for four years. No history of previous illness. Patient suspected herself that the disease was due to infection from a child she had nursed, but as no history could be elicited of ulceration in other regions, or of other signs of constitutional infection and her youngest child (the ninth) was apparently perfectly healthy, I was inclined to look upon the case as one of simple ulceration caused by pressure. The ulcer was circular and rather superficial and covered with adherent crusts, in the removal of which its surface was found to be covered with small indolent granulations. Around the ulcer the skin was thickened and eczematous.

Ordered five grains of dried thyroid extract daily, dose to be increased in ten days to ten grains daily. March 31st, for the last ten days patient has been taking ten grains daily. The ulcer has changed decidedly in appearance, the edges being more ragged, but its surface is covered with larger and more luxuriant granulations. Drew the edges of the ulcer together with narrow strips of adhesive plaster and dressed with two per cent. carbolized water and dusted with equal parts of salicylic acid and zinc oxide powder. Patient says that she suffers occasionally from nausea after taking the extract, but she presents no symptoms of thyroidism, so the dose of the dried extract was increased to twenty grains daily. For the relief of constipation from which she complains a laxative pill was ordered.

April 21st.—Marked improvement; the ulcer now showing evident signs of healing. Twenty grains of the extract having caused symptoms of thyroidism, *i.e.*, faintness and excited action of the heart, patient had been obliged to reduce the dose of the extract, and for the past week has taken from two to three 5-grain tablets daily.

June 25th.—Soon after last visit ulcer healed entirely, and the skin of the foot became perfectly smooth, A week or two ago, however, the skin became again slightly ulcerated and an eczematous eruption appeared on the ring finger of the right hand. Ordered ten grains daily.

April 12, 1896.—Patient reports that for one month after her last visit she took daily the dose then ordered. At the end of that time she found that the ulcer had entirely healed and she has had no recurrence of it. It may be interesting to note that the patient, a very stout woman, has during the somewhat prolonged thyroid treatment, to which she has been subjected, observed none of the loss of weight, which has sometimes been observed as the result of thyroid feeding.

[2] *British Medical Journal*, July 7, 1894.

ROMAN FEVER is almost a thing of the past. From 650 in 1881, the deaths from malaria ran down to 254 in 1891, while for the last five years the average has been 149, the number in 1895 being 125. These figures are all the more significant in that the population of Rome has increased from 300,000 to 467,000 in fifteen years. An equally remarkable diminution has taken place in the death rate for all other infectious diseases, so that Rome, even in the traditional unhealthy season, is one of the most healthy capitals in Europe.

THE SURGICAL TREATMENT OF ROUND ULCER OF THE STOMACH AND ITS SEQUELÆ, WITH AN ACCOUNT OF A CASE SUCCESSFULLY TREATED BY LAPAROTOMY.

By R. F. WEIR, M.D.,
OF NEW YORK;
SURGEON TO THE NEW YORK HOSPITAL, ETC.,
AND
E. M. FOOTE, M.D.,
OF NEW YORK;
SURGEON TO THE RANDALL'S ISLAND HOSPITALS.

(Continued from page 462.)

Prognosis.—The mortality which has followed laparotomy for perforated gastric ulcer is thus far about seventy-one per cent. If what has already been said of the value of early diagnosis and prompt operation needs further emphasis, it finds it here; for the table shows that more than half of all the cases operated upon in the first twelve hours recovered, the mortality being thirty-nine per cent., while of those operated upon from twelve to twenty-four hours after perforation, seventy-six per cent. died; and of those who came to operation after the first day, eighty-seven per cent. succumbed.

Treatment.—If perforation be suspected, and until a diagnosis is arrived at, nothing should be given by the mouth. This also means that lavage should in no such case be resorted to. By neglect of this latter rule, rupture of a weakened stomach, and extravasation of gastric contents into the peritoneal cavity, have been known to occur in two cases in this city. Unfortunately, perforation often takes place when the stomach is full. If such a condition is recognized, and the diagnosis of perforation is made, surgical interference is the more imperative. If in doubt, therefore, the patient should be kept quiet and in a horizontal position. If the symptoms of collapse or pain are urgent, such stimulants and anodynes as are needed should be administered by the rectum, or hypodermically, with the employment of external warmth, etc.

For the required laparotomy the incision is best made in the median line, and should be an ample one, that is to say, three to five inches long. If more room is required it can readily be obtained by a crosscut through either the right or left rectus muscle. An incision to the left of the median line has been advocated,[1] in order to render more accessible the cardiac end of the stomach. This, however, is better determined after the exploration has been made through the median incision.

[1] Morse, *Lancet*, 1894, i, p. 672.

The liver is to be lifted up by the hand of an assistant or by broad retractors, and the stomach gently drawn downward, and to one or the other side. Gentle squeezing of the organ will often expose the perforation by the escape of gas or fluid. If nothing is seen on the anterior surface, the lesser omentum is to be torn through at a thin place near the stomach (to avoid the colonic circulation), and the posterior wall explored, as much as possible. With the aid of a sponge on a clamp, through this same opening, the recesses of this cavity can be reached to search for extravasated fluid.

If any recent adhesions exist about the perforation it is wiser to separate them, after protecting, as far as possible, the adjacent parts by gauze or sponges, and thus to find and to suture the gap than to trust to the fibrinous closure. The pressure of the finger-tip will temporarily occlude the opening in the stomach until the protecting pads are arranged, if this has not already been done, and will also aid in safely applying the first occluding sutures. In three of the cases recorded in Table I, such fibrinous adhesions were left undisturbed. Two of these cases died, and at autopsy it was seen that the fibrin obscured the perforation, but did not really close it. The third case recovered—a result which might have been true of all three, had sutures been applied.[1]

The excision of the ulcer has been advocated by some. On the other hand, it has been objected, with much reason, that this is unnecessary, that it takes valuable time, that it makes a larger and more difficult opening to close, and that hemorrhage follows, which is very detrimental to the patient, and is often troublesome to check. In only three of the twenty-three successful cases was the ulcer excised. Of the remaining twenty, seventeen were sutured, Lembert style, while two of the others were tamponed, suture being impossible, and in the other case the fibrinous adhesions were not disturbed.

Lavage, through the perforation, as some have practised it, is inadvisable. Lavage, but not hyperdistention, after the operation, by the usual method, is advisable, not only to empty the stomach thoroughly, but also to test the security of the stitches. The stomach should be left empty, to avoid vomiting and all strain on the suture.

[1] The search for a perforated ulcer is not always easily made, and often demands considerable manipulation and time. Too often, from the lateness of the operation, the patient's waning strength will forbid its thorough performance. Twice has it happened to me to be compelled to desist from further exploratory effort, and to find only at autopsy, the sought-for perforation.
R. F. W.

In twelve of the successful cases, irrigation of the peritoneal cavity was resorted to. In eight cases no irrigation was employed, but the peritoneum, when soiled, was cleansed with gauze. As regards the fluid used for irrigation, it was in three cases boiled water, in two cases a weak solution of carbolic acid, and in one case a solution of boric acid. In six cases the character of the fluid is not given. Concerning this practice, a safe rule would seem to be not to irrigate if the amount of escaped fluid is small. Sponging with boiled water will then suffice. If, on the other hand, much fluid has escaped, and the peritoneum has been extensively involved, the best chance for the patient lies in using large quantities of hot fluid, so as to wash clean every part of the peritoneum. For this purpose, sterilized salt solution, 0.6 per cent., at 105° F., is advisable, and in these cases special drainage posteriorly on both sides, and in the pelvis, is to be resorted to. Five successful cases were drained; in ten no drainage was employed.

DUODENAL ULCERS.

What has been said of perforating ulcers of the stomach, as to diagnosis and treatment, applies equally to acute perforating ulcer of the duodenum. Before an exploratory laparotomy, the two are practically indistinguishable. Perforating ulcer of the duodenum is confined almost exclusively to men, but it occurs in them at the same age as does perforating gastric ulcer, *i.e.*, from the twenty-eighth to the forty-fifth year. The perforation occurs, as will be seen from Table II., most frequently (seven out of nine cases) in the anterior wall of the bowel, and in but one case was there an associated abscess. This fact is an important one. Out of the nine cases, one survived, to die two months later from an intestinal obstruction from adhesions which resulted from the operation; while, in another case, a second operation was performed on the twenty-fifth day after the first one, to evacuate pus between the liver and diaphragm. The patient ultimately recovered.

In concluding this brief of the operative procedures for the relief of perforating gastric ulcers, let us strongly emphasize the fact, which is here established, that the happy result of operation is dependent more upon its early performance than upon any other factor. And with this in mind, it should be wholly unnecessary to urge again every physician to acquaint himself very fully with the early symptoms of such a perforation.[1]

[1] In addition to the references already given, an article by Gilford in the *Lancet*, 1894, i., p. 1369, and one by Kriege in the *Berl. klin. Wochenschr.*, 1892, p. 1280, give a good idea of the subject.

SUBPHRENIC ABSCESS.

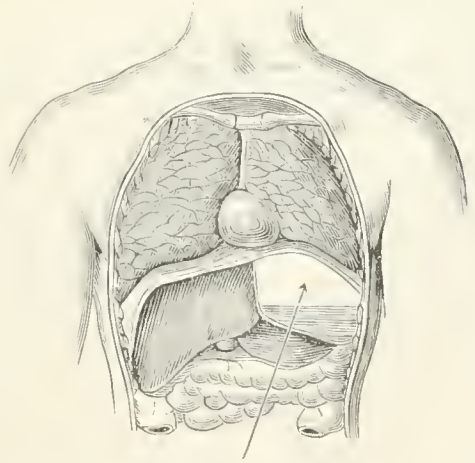
In quite another way, a gastric ulcer may perforate and cost the life of a patient, viz., by the formation of an abscess to the right or left of, or behind the stomach. To this condition several names have been applied, of which *subphrenic abscess* seems most likely to survive.

Etiology.—Subphrenic abscess may also arise from other than gastric lesions, and numerous cases have been reported as coming from diseases of the gall-bladder, liver, spleen, kidney, duodenum, and appendix. The etiology in some of these cases is questionable. Certainly, the stomach and appendix are responsible for the large majority of the abscesses that form under the diaphragm.

Penrose and Dickinson[1] state that of ulcers of the stomach only those cause abscess which are situated in the posterior wall; but others admit that an ulcer in the anterior wall, if near the cardiac orifice, may also give rise to an abscess. Weir has observed two cases in which an abscess formed between the stomach and spleen. In one of them the source of infection was a gangrenous appendix; in the other, an anterior perforation of the stomach.

Pathology.—The pus may be situated extraperitoneally,—which is rare, and is commonly then of renal origin,—or it may occupy some portion of the lesser peritoneal cavity, or be limited to the space between the cardiac end of the stomach, diaphragm, and spleen (or liver, if on the right side). It rarely breaks into the general peritoneal

FIG. 1.



Left-sided Subphrenic Abscess (containing gas). From Beck.

cavity, but progresses slowly, pushing up the diaphragm on the affected side, and frequently bursts into the pleural cavity or lung.

[1] Penrose and Dickinson, *Br. Med. Jour.*, 1893, i., p. 118.

Through the courtesy of Dr. A. J. McCosh, the following unpublished case of an anterior abscess from a gastric perforation is here inserted. The patient was operated upon by him in November, 1895, at the Presbyterian Hospital, and the perforation in the stomach successfully sutured.

A female, aged thirty, had obscure gastric symptoms for years, with occasional vomiting. The onset of perforation was not sudden, but there was slowly increasing epigastric pain and tenderness, lasting for five or six weeks, with constipation, moderate tympanites, and fever. Laparotomy disclosed an abscess between the left lobe of the liver and the lesser curvature of the stomach, holding about three ounces of pus. The perforation in the lesser curvature was still patent, and admitted the index finger. It was sutured, and the patient made a good recovery. Five months later, she was reported in fairly good condition.

In a similar case, also unpublished, Dr. Abbe reached and drained the abscess and sutured the perforation after excising the ulcer. The result, as far as the stomach was concerned, was perfect; but the inflammatory process had already invaded the diaphragm, and the patient died, at the end of eighteen days, of purulent pleurisy.

Melzer[1] has collected 110 cases of subphrenic abscess, in which only 5 of them were bilateral. Of the 48 unilateral cases occurring in women, 34 were on the left side, while of 57 unilateral cases in men, only 13 were on the left side. These figures are explained by the causes of the abscesses, which were: Gastric ulcer, twenty-eight times in women, four in men; duodenal ulcer, seven times in men, two in women; appendicitis, eleven cases in men, two in women.

Four cases are on record[2] in which a gastric ulcer has ended by perforation into the left ventricle of the heart, with immediate fatal hemorrhage.

Diagnosis.—At all stages in the development of a subphrenic abscess the physical signs are complex, and the diagnosis is one to tax the powers of the best observer. From one-third to one-half of the abscesses contain gas[3] (see Fig. 1), in which case the expected dulness will give place to a tympanitic resonance. Inasmuch as the diaphragm is involved in the inflammation, a serous pleuritic effusion may also result to add to the confusion. Pus and gas may likewise be found in the pleural cavity, if the diaphragm is perforated.

Before a perforation of the diaphragm has occurred the absence of Litten's "diaphragm phenomenon" associated with dulness over the lower thorax, not due to liver or spleen, may be suggestive of subphrenic abscess.[1] This "diaphragm phenomenon," which is not as well known as it should be, is the visible sucking-in of the lower intercostal spaces, one after the other, corresponding to the descent of the diaphragm. If the phenomenon is present on one side and absent on the other, there exists on the side on which it is absent either fluid or gas in the pleural cavity, pneumonia of the lower lobe, or a subphrenic abscess; for it is in these conditions that one is most likely to have a one-sided arrest of the muscular action of the diaphragm from inflammatory paralysis. The impairment of diaphragmatic motion is stated to be present in seventy per cent. of the cases of subphrenic abscess. The clinical value this test, however, remains *sub judice.*

The aspirating needle is another valuable aid in diagnosis, although owing to the cheesy character of the pus, several punctures and a large-sized needle may be necessary to obtain a positive result. If pus is found it will sometimes flow *out* in *inspiration* and not in expiration, thus indicating that the pus is below the diaphragm and not above it. If the needle enters a gaseous cavity a similar motion is communicated to the current of air, as shown by a monometer,[2] or by the effect on the flame of a match held close to the opening of the cannula, a test which Weir[3] found of value in one case. Further, the butt of the needle may be seen to rise on inspiration, since the descending diaphragm carries the point with it, and the chest wall forms the fulcrum; but, here too, paralysis of the diaphragm may interfere seriously with this as in nearly all of the tests. Indeed, in a recent case, Maydl,[4] with all his experience, was only able to establish a diagnosis after opening the abscess and cutting out a piece of its superior wall, and submitting the same to a microscopical examination, which revealed its muscular structure.

Prognosis.—Spontaneous recovery is very rare, but it has been reported, even when complicated by purulent pleuritis.[5] Barton[6] mentions the case of a woman, aged thirty-seven, who had been treated for years for gastric ulcer, with hematemesis, etc. One day she had severe pain, and vomited a quantity of dark material. The pain and vomiting continued for four weeks with subnormal temperature, as low as 95° F., and never

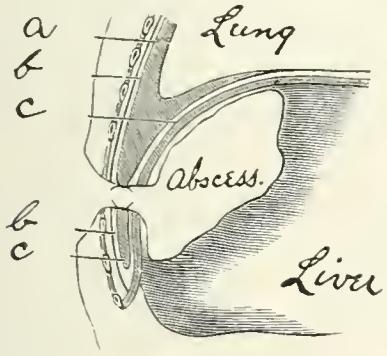
above 99° F. She was given nutrient enemata and large doses of opium. At the end of the fourth week she passed a quantity of offensive pus per anum. From that time, there was a daily evacuation of pus, diminishing from about six ounces until it ceased, three weeks later. She was fed for six weeks almost entirely by the rectum. Recovery was perfect.

Such cases as these are to be looked on as happy accidents, and have no effect on a rational treatment. Left to itself, the abscess usually perforates the diaphragm,—on the left side, if of gastric origin,—and the patient succumbs to the septic products in from one to three months.

The treatment consists in the location and evacuation of the pus. If aspiration through the seventh, eighth, or ninth intercostal space procures pus, it is a very simple procedure to let it out thoroughly and drain the cavity, either by a thoracic incision, or by resection of a portion of the rib. If aseptic precautions are observed in the aspiration, and in the subsequent operation, and, what is the most important, if the diaphragm and pleura are stitched together, before the former is

Fig. 2.



Thoracic Opening in Subphrenic Abscess. From Beck.
a, pleural cavity; *b b*, costal pleura; *c c*, diaphragmatic pleura. At the opening the two layers of pleura (costal and diaphragmatic) are represented as sewed together, above and below.

incised, as suggested by Volkmann and Thornton, it is entirely possible to protect the pleural cavity from infection. Sometimes the prominence of the abscess in the epigastrium leads to an incision in that region; and several cases have been reported when the abdomen was opened in the left hypochondrium. In other cases, especially of the rarer extra-peritoneal variety, the lumbar incision proves most satisfactory.

Maydl,[1] whose exhaustive consideration of the subject of subphrenic abscess has justly received wide notice, was able to collect only ten cases of operation with three recoveries. Comte[2] found thirteen others with eight recoveries. Beck[1] has recently contributed three successful cases. Abbe has had two fatal cases, and Weir, five, with a similar result, making with McCosh's case, a total of thirty-four operations with fifteen recoveries. Several of these operations were performed at too late a period, when abscesses in thoracic or abdominal organs made death inevitable.

Eight times the incision was made in the epigastrium with five recoveries, in only one of which was suture of the associated gastric perforation attempted. Such a procedure is often very difficult on account of the adhesions, and, moreover, in several autopsies it appeared that the ulcer had entirely closed by cicatrization.

Of the two cases where the incision was made in the left hypochondrium, in one, the stomach was sutured with great difficulty, and death followed leakage in the suture line; in the other, no suture was attempted, and the patient recovered. Hence, one may safely leave the gastric opening to close by cicatrization, or by a secondary operation, if necessary. In eight cases the abscess was relieved by thoracotomy; of these, five recovered; three, complicated respectively by gangrene of the spleen, abscess of the spleen, and extensive suppuration, succumbed.

Cramer[2] has recently reported two successful cases operated upon by Bardenheuer. The pus in these cases was from an unusual source. In one case, situated on the left side, it originated from a splenic abscess, while in the other it started from an inflamed Fallopian tube, and developed between the liver and diaphragm on the right side.

One is justified, then, in concluding that if an abscess can be located with an exploring needle before serious organic lesion has occurred, that surgery offers a good chance of recovery, while therapeutic measures have little power to avert a fatal issue. Comte says "the prognosis of infra-diaphragmatic abscess of gastric origin is fully as grave as that of diffuse peritonitis." Attempts at evacuation of the contents of such abscesses, through a large needle, are universally condemned, and the incisions made for their relief should be free, and often associated with posterior drainage.

Operations for Non-perforating Gastric Ulcer.

The surgical treatment thus far discussed considers only perforated ulcers and their sequelæ; but without perforation a gastric ulcer may give rise to symptoms for the relief of which an oper-

[2] Cramer, *Deut. Zeit. f. Chir.*, 1896, Vol. xlii,. p. 597.

ation is indicated. Of these conditions may be mentioned

ADHESIONS RESULTING FROM GASTRIC ULCER.

Thus, as the result of ulceration, adhesions may be formed between the wall of the stomach and the contiguous structures. If the ulcer is situated posteriorly, the cicatrix thus formed is usually the most favorable termination of the trouble. If a movable portion of the stomach is involved, symptoms may result, not only those produced by a perforation or by an abscess formation, which have been already spoken of, but such as result from traction on adhesions of lesser or greater extent. Hahn[1] found in one case five separate old adhesions between the stomach and transverse colon, which he divided, and thus cured the patient of pain which had existed for years. Similar cases in which there were adhesions between the stomach and the liver have been operated upon by Rosenheim, Robson,[2] Perrier,[3] and Lauenstein.[4] In four of these cases the operation was a complete success; in three others the relief obtained was only temporary. In all of these cases the adhesions were of slight extent.

Mikulicz[5] had a case in which the stomach was adherent to the abdominal wall. He was able to divide the adhesions and free the viscus, to the complete relief of the patient. In two similar cases—one in charge of Billroth[6] and one of Hofmeister,[7] the stomach was torn in the attempt to divide the extensive adhesions which bound it to the abdominal wall. The underlying adherent portion of the stomach was thereupon excised, and the opening so made was duly sutured. Both patients recovered. In Hofmeister's case the opening in the stomach was as "large as a saucer," and it was found necessary to suture it transversely, in order to avoid undue constriction of the organ.

These three cases gave essentially the same history of gastric trouble for years, marked by epigastric discomfort, which was aggravated by food to a colicky pain, with occasional vomiting and loss of flesh and strength. In each case there was a well-marked tumor in the epigastric region, adherent to the abdominal wall.

Occasionally the surgeon may find presented to him, in a rather acute case, after the ventral abdominal incision has been made, that he has happily interfered, when limiting adhesions have recently shut off either a completed or a progressing perforation. These cases are properly to be considered under the first division of our subject, but can be touched upon here. The case lately presented by Dr. Parker,[1] and included in Table I, was of this kind. On the anterior wall of the stomach was found a mass of adhesions, soft in character, on separating which an incomplete perforation was seen and felt. This was packed with iodoform gauze and the tract left to granulate. The patient made a satisfactory recovery.

PYLORIC STENOSIS.

Of this, which is somewhat beyond our theme, it may be said shortly, that it has long been recognized that the ulceration of the pylorus and the contraction of the inflammatory tissue, which it occasions, are responsible in its acute condition for the pain, hemorrhage, and sundry disorders of digestion, and in its chronic form for the conjoined dilatation of the stomach. For its relief, the stretching of the contracted pylorus, suggested by Loreta, has so often been followed by recontraction, as now to have become an obsolete practice. The cure of such narrowings may be secured by the ingenious procedure for the enlargement of the contracted pylorus of Heineke-Mikulicz, which converts a horizontal incision into its lumen into a vertical one through transverse suturing.

Pylorectomy, a formidable operation, has several times been successfully performed for gastric ulcer at or near the pylorus. Comte[2] mentions five successful and three unsuccessful cases of pyloric resection. In three of these there was a dense tumor, which until operation was supposed to be carcinomatous, and in two of these instances its true nature was determined only after microscopical examination.

The chief objection to the pyloro-plastic operation is its high mortality. In the hands of one of its originators, Mikulicz,[3] it has a mortality of over fifty per cent. If it should be continued at this rate gastro-enterostomy should preferably be resorted to.

IRREGULAR GASTRIC CONTRACTIONS.

Allied to the foregoing complications of a gastric ulcer is the hour-glass stomach from a cicatrized ulcer. This rare condition has three times been operated upon in substantially the same manner; viz., by establishing an anastomosis be-

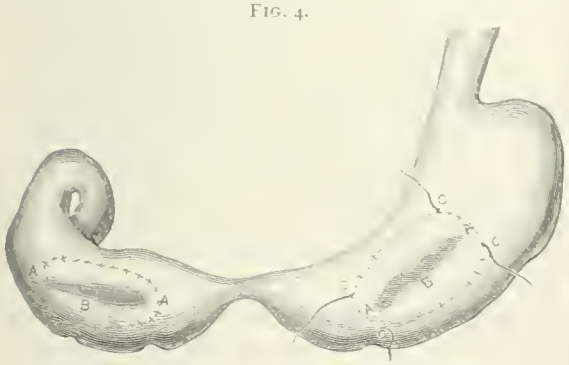
tween the two halves of the stomach. Wölfler[1] reported a successful case of this kind. In Eiselsberg's[2] case the suture leaked and the patient died of peritonitis. Watson[3] of Boston, has lately published a third case, in which the structure was so firm and small, as barely to admit the little finger introduced into it from without the stomach. The symptoms of pain, nausea, and vomiting, which had been growing more marked since their beginning, five years previous to operation, were entirely relieved by the anastomosis, and in five months she had regained twenty-two of the forty pounds in weight, lost in the year preceding operation.

Fig. 3.

Shows the position of the stricture.

The diagrams (Figs. 3 and 4), sufficiently illustrate the condition of the stomach and the operation done to relieve it. The suture was first completed, apposing the walls of the stomach, and then the anastomosis was established. It was accomplished, and this is Watson's modification of the operation, by an incision made in the

Fig. 4.



The stomach is here represented as being turned back to its original position in order to show the form (A A A A) of the sutured areas which united the two parts of the stomach. The communicating incisions (B B) and the position of the four long sutures (C C C C) which served as guides to indicate the limits of the sutured areas.

superimposed stomach. Through this opening, another cut, through the two already applied gastric walls, was carried with exactness into the subjacent or cardiac end of the stomach. After this was finished, the first incision, *i.e.*, that made in the pyloric end of the stomach, was closed as usual by sutures, as is shown in Fig. 4.

Gastro-enterostomy is a preferable operation. The anastomosis can either be a single one posteriorly at the stenosed part, conjoined with a Mikulicz-Heineke incision anteriorly at the same location, or a double gastro-enterostomy may be performed, tapping each sac of the stomach.[1]

RESECTION OF ULCERS NOT IN THE PYLORUS.

As long ago as 1882, Czerny[2] opened the stomach of a man aged forty-two, who had suffered for two years from incessant pain and vomiting. He found a large ulcer in the posterior wall and lesser curvature. A part of it was scraped out thoroughly, and a part was excised. The patient recovered, and in three months he had gained over forty pounds in weight.

In 1888, Cordua[3] reported the resection of an ulcer of the anterior wall of the stomach of a woman of forty-six years of age. The ulcer formed a movable tumor, easily palpable in the left hypochondrium. Its excision was attended by complete success, and the relief of a severe gastralgia of ten years' duration.

Two cases of successful resection of an ulcer adherent to the anterior abdominal wall have been referred to under adhesions. One of the most instructive of these cases is that of Schuchardt,[4] who excised an ulcer in the lesser curvature of the stomach. Two weeks later the patient died, and on autopsy, a second ulcer was discovered, larger than the first, and in a scarcely accessible situation, for a careful search with the hand (*sic*), introduced into the stomach at the operation, did not reveal it.

Keen[5] has also, with success, resected (in 1892) a gastric ulcer, supposed to have been a carcinoma from its symptoms, but which was probably a chronic simple ulcer, from the clinical aspects, the patient yet living, four years after the operation.

In the preceding cases the general sufferings of the patient determined the operation. But resection of a gastric ulcer has also been performed for hemorrhage. Roux[6] reported to the French Congress of Surgeons in 1893 that he had excised a small ulcer in the lesser curvature of the stomach of a man who was very anemic from two copious hemorrhages. The ulcer had eroded the coronary artery. This vessel was ligated and the opening

in the stomach sutured in three rows. The patient recovered.

Mikulicz[1] had a similar case, also involving the coronary artery, in which resection of the ulcer was likewise successful.

From this meagre number one can appreciate the sentiments of surgeons in connection with a condition that appeals strongly to their art for relief. In 1892 it was urged[2] that more boldness should be had in treating this symptom, which gave a higher mortality when treated expectantly than is generally believed; for Muller, in 127 cases of gastric ulcer, found hemorrhage to occur in 37 instances, and of these 14 were fatal, and that the treatment of this condition should not be postponed until the loss of blood had dangerously weakened the patient, and thereby lessened his chances of recovery.

But experience gathered since then has shown some unexpected difficulties which are likely to be encountered, one of which is illustrated by the case of Schuchardt just quoted, where great difficulty was experienced in finding the ulcer or all of the ulcers. There are ulcers where the thickening is so great as to form a tumor easily felt through the abdominal wall, or, as in our successful case, to be detected on palpating the exposed stomach; while in other cases it is difficult to recognize an ulcer by sight or touch, even after the stomach has been widely opened. In one of the cases already quoted, Abbe of this city, in his search for a gastric ulcer, made an incision in the anterior wall of the stomach 1½ in. long. Through this the stomach wall was everted, the opening being shifted in various directions for this purpose, but no ulcer was found; though at the autopsy later, several ulcers were seen to be present. And the writers of this article have recently seen at autopsy two cases in which an operation had been refused, and in which death followed repeated copious hemorrhage. In both cases the ulcer was so minute that it was difficult to find it when the whole stomach was spread out in a good light. In one of the cases its presence was positively shown only by transmitted light, which revealed a slight thrombus in the eroded vessel, situated in an otherwise bloodless stomach wall.

In cases like these the chance of finding the ulcer at the time of the operation, unless the vessel is bleeding, is practically *nil*. It is doubtful whether the illumination of the stomach, held up while an electric light is passed into it, or behind it into the lesser peritoneal cavity, would assist in the location of the ulcer; but this idea was suggested by the difficulties in Abbe's case. This case, as well as that of Schuchardt and others, presented the further difficulty of a multiplicity of ulcers. Even if found, they are not always in the same neighborhood; and a double or triple resection would add greatly to the severity of the operation.

In such a dilemma, the suggestion made by Doyen,[1] and practised by him in twenty-nine cases, seems worthy of consideration. It is the systematic application of rest to the ulcerated stomach, by means of a gastro-enterostomy, just as an ulceration of the rectum is often well-treated by a colostomy, or as a painful bladder is relieved by a suprapubic opening. The results in his own gastro-enterostomies, as well as those of other surgeons, prove that when this artificial pylorus is well-established that ulcers quickly heal and hemorrhage ceases.

But the question as to the risk of operation at once arises. What is the danger, on the one hand, from the operation *per se*? And, on the other hand, what is the danger to the patient from the ulcer if let alone? It is not easy to obtain the mortality from gastro-enterostomy in benign cases, and our information is therefore scanty. We present, however, for purposes of comparison, the following figures: Mikulicz[2] operated twenty-eight times, with nine deaths (thirty-two per cent.). Most of his cases were carcinomatous. Also that Murphy[3] has collected reports of cases, nearly all carcinomatous, in which his button was used to perform gastro-enterostomy. Of these sixty-one cases, twenty-eight (or forty-six per cent.) died from the operation. More to the point is the testimony of Haberkant[4] who states that the mortality following forty-seven gastro-enterostomies for benign causes, which he had collated, was twenty-five per cent. In contrast to these figures are the results of Doyen,[5] who reported to the last French congress of surgery that he had performed gastro-enterostomy twenty-nine times, with three deaths. The operations were nearly all performed for ulcer, pyloric spasm, or gastric dilatation due ulcer or pyloric fissure(?), only a few cases being cancerous. As two of the fatalities occurred in the cases of cancer, his record in benign cases is nearly perfect. Unfortunately, details of the cases operated upon are not given.

[4] Haberkant, *Arch. f. klin. Chir.*, 1896, vol. li., p. 861.
[5] Doyen, *Rev. d. Chir.*, 1895, p. 911.

When we try to estimate the risk to the patient from a gastric ulcer not surgically treated, we find that, according to the best authorities, from ten per cent. to fifteen per cent. of all cases die from perforation, and an additional three per cent. from hemorrhage. To this must be added a further small percentage in which ulceration ends in carcinoma (Comte says that from four to nine per cent. of the cases of malignant disease of the stomach develop in the base of a simple ulcer), and another percentage of patients who die slowly from pyloric stricture, adhesions, etc.

From all these data, it is safe for comparison to infer that about one-fifth of all the cases of gastric ulcer which are treated medically, die. This is properly to be contrasted with the reliable figures of Haberkant, who has shown, as just stated, that, by gastro-enterostomy, the least dangerous of surgical operations proposed to cure a gastric ulcer of severity, a mortality of twenty-five per cent. is to be expected.

The difference in the mortality given by Doyen, and that by other surgeons, is hardly to be accounted for by the slight improvement suggested in the former surgeon's technic. This consists[1] mainly in first tucking the greater omentum backward into the lesser peritoneum through a hole made in the gastro-colic omentum, and then stitching the colon to the stomach in order to save the dragging of the parts on the jejunum when the latter is attached by the gastro-enterostomy, which is now finally completed.

The application, therefore, of the operation of gastro-enterostomy for the relief of gastric ulcer, producing repeated hemorrhages, severe and prolonged pain, or obstinate vomiting (Doyen's formal indications for operation), while it is attractive in principle and meets well the difficulties of the other operations that have been practised, must be considered to be temporarily in abeyance.

The operation of gastro-enterostomy is yet unsatisfactory in its details. This is acknowledged by surgeons of experience, and is further proven by novel methods for its performance that are evolved at short intervals. The gastro-enteric opening can be readily effected, but the free current of the food, and particularly the bile, to the intestines below is not always safely accomplished, and in this respect the operation is individually felt to be a yet unsolved problem. Should, however, the improvement, suggested by Doyen, be corroborated at the hands of other surgeons, or perhaps even be bettered by them, the employment of the operation of gastro-enterostomy for the relief of the painful and less urgent forms of gastric ulcer would at once enable relief to be given to many, and our art to be notably amplified.

CLINICAL LECTURE.

INFECTED ATMOSPHERE.[1]

By GUY HINSDALE, M.D.,
OF PHILADELPHIA.

THE air we breathe is a fertile subject for scientific investigation. Twenty years ago we knew comparatively little about the organic constituents of the atmosphere. Beyond the evidence of our senses in detecting bad air, prompting us to apply the general principles of ventilation, and beyond the well-grounded belief and knowledge that change of air to the mountain or the sea would favor the recovery of cases that resisted other measures, little was known.

Three names stand out prominently in the work which marks the beginning of a new epoch in this field—Pasteur, Tyndall, and John Bastian. Although the labors of the last-named investigator were extensive, and his conclusions produced an immense impression at the time they were published, they were entirely overthrown by Tyndall and Pasteur, and have now nearly passed into oblivion.

Bastian, twenty years ago, championed the doctrine of spontaneous generation. But the best minds of England and France not only proved him incorrect, but rapidly established the fact that all germs come from pre-existing germs, and that germ-life cannot arise *de novo*. Every one among us knows to-day that every aseptic dressing, every aseptic solution, so remains, provided it be not contaminated from without. The purest air we ever breathe contains some particles in suspension. This floating matter may be entirely innocuous, or it may consist of dangerous germs that seek lodgment in our throats, our lungs, our intestines, a crevice in the skin, or some other vulnerable point. Besides the floating matter in the atmosphere, embracing many germs that are well-known to be virulent, it has been commonly believed by physicians and sanitarians "that the discomfort and dangers to health and life which had been known to exist, sometimes at least, in unventilated rooms occupied by a number of human beings, were largely or entirely due to peculiar organic matters contained in the air expired by these persons, and that the increase in carbonic acid due to respiration had but little effect in producing these results, its chief importance being that it furnished a convenient means of determining the amount of vitiation of the air." In this connection I take the opportunity of calling attention to the latest researches on this subject, just published as one of the "Smithsonian Contributions to Knowledge," by Drs. John S. Billings, S. Weir Mitchell, of our own staff, and Dr. D. H. Bergey of the Laboratory of Hygiene of the University of Pennsylvania.

Experimenters hitherto have reported various results,

[1] Delivered before the Class of Nurses in Training at the Orthopedic Hospital and Infirmary for Nervous Diseases, Philadelphia.

but the majority have, of late, denied that the exhaled breath of healthy human beings, or of animals, contains a poisonous or organic alkaloid, or any poisonous product other than carbonic acid.

Dr. Bergey began by causing a man to breathe for from twenty to thirty minutes so that the expired air should pass through sterilized melted gelatin, which was then preserved as a culture for from twenty to thirty days. In the first trial six, and in the second two colonies of common air organisms developed; but when special care was taken to thoroughly sterilize the vessels used, the result was that in two consecutive trials the gelatin remained sterile. Epithelial scales and other matters were sought for by condensing the vapor of the exhaled breath and examining the product with the microscope. In six preparations thus made no bacteria or epithelial cells were found.

Experimenters in this field find that in one day a healthy man will exhale over a thousand gallons of air, and from six to twelve ounces of moisture. There is more or less ammonia in the product exhaled, the more where the teeth are allowed to decay and proper cleanliness is not observed. In examining the breath from a consumptive Dr. Bergey found that the fluid contained a smaller proportion of ammonia, and a larger amount of oxidizable matter than did fluid similarly collected from a healthy man. No organic alkaloids were found.

It was found in attempting to condense the moisture of the air of hospital wards that the placing of a dust filter in front of the condensing apparatus causes a marked reduction in the proportion of ammonia in the condensed fluid.

Drs. Billings, Mitchell, and Bergey, made a series of experiments by injecting into animals the fluid condensed from the air expired by healthy persons, and also by a man, whom you may remember to have seen in our clinic, whose larynx has been removed and who breathes through a tracheal fistula. In the last case the possibility of contamination of air in the mouth was of course excluded. The injections were made into the general circulation in rabbits, guinea-pigs, and white rats. The results of the subsequent examination showed that there was no special disease or degeneration in the organs of these animals; in other words, there was no organic poison.

The conclusion from this experimental work is that the injurious effects of air expired by healthy animals and men are due entirely to the diminution of oxygen, or the increase of carbonic acid, or to a combination of these two factors. It would appear also quite improbable that the minute quantity of organic matter contained in the air expired from human lungs has any deleterious influence upon men who inhale it in ordinary rooms, and hence it is probably unnecessary to take this factor into account in providing for the ventilation of such rooms.

The experiments showed, secondly, that in ordinary quiet respiration no bacteria, epithelial scales, or particles of dead tissue, are contained in the expired air. But in the act of coughing, or sneezing, such organisms or particles may probably be thrown out.

Thirdly, the ammonia exhaled is chiefly due to the products of decomposition of organic matter, which is constantly going on in the mouth and pharynx.

Fourthly, the air of hospital wards was found to be contaminated chiefly by minute particles—dust. This contained micro-organisms capable of producing inflammation and suppuration.

Fifthly. No peculiar volatile poisonous matter in the air expired by healthy men and animals was found, save carbonic acid.

It was also found in these investigations, as in others preceding them, that animals may be habituated to an atmosphere so vitiated by a loss of oxygen and an increase of carbonic acid, that a similar animal brought into it from fresh air dies almost immediately. It would appear that immunity to vitiated air may exist normally in certain mice, or be produced in them. It would be an interesting research to determine what races of men can endure the greatest foulness of atmosphere. One who reads the testimony of Arctic explorers, from Dr. Kane to Caspar Whitney, cannot fail to be impressed by the tolerance which the Esquimaux Indians show in this regard.

In the excessive cold of the Arctic regions the consumption of oxygen increases as the temperature diminishes, and the demand for oxygen is more urgent than in temperate climates. Drs. Billings, Mitchell, and Bergey, say that the proportion of increase of carbonic acid and of diminution of oxygen, which has been found to exist in badly ventilated schools, theaters, or barracks, is not sufficiently great to satisfactorily account for the great discomfort which such conditions produce in many persons, and there is no evidence to show that such an amount of change in the normal proportion of these gases has any influence upon the increase of disease and death-rates, which statistical evidence has shown to exist among persons living in crowded and unventilated rooms. The causes of the increased death-rate under these circumstances are chiefly pulmonary tuberculosis and pneumonia arising from the access of infected dust to the air passages. It is also pointed out that impure atmospheres may affect the vitality and bactericidal powers of the cells and fluids of the upper air passages with which they come in contact, and may thus predispose us to infections, the potential causes of which are almost everywhere present, and especially in the upper air passages and in the alimentary canal of even the healthiest persons. Whether such be the cause or not we do not know; future studies may enlighten us.

The recent observations[1] of Dr. Irwin H. Hance at the Adirondack Cottage Sanitarium ought to dispel some of the ill-grounded fears of the danger of contracting tuberculosis by mere contact with patients suffering from this disease. Needless prejudice has no doubt been aroused by ignorance of the precise manner in which tuberculosis may be communicated and hardship entailed on the unfortunate subjects. We know that hospitals, private dwellings, and conveyances do become infected, but we doubt if the patient infects by mere contact, much less by his breath. It is through the sputum, when dried and distributed through the atmosphere, that the chief mode of infection operates. Dr. Hance quotes the investigations of Celli and Guarnieri, who found the expired air of tubercu-

[1] *Medical Record*, New York, December 28, 1895.

lar patients free from tubercle bacilli, and also that air blown by a bellows over and through sputum very rich in bacilli remained free from these germs. Seven other experimentors made similar observations. For two months Tappeiner[1] caused a woman with advanced phthisis to cough through an opening into a wooden box in which were two guinea-pigs; at the end of that time they were killed and found to be sound.

I report Dr. Hance's observations as they are of great practical value to a proper understanding of this subject. Dr. Hance examined the dust taken from eighteen buildings belonging to the sanitarium, some of these having been occupied for eleven years by consumptives. The dust was taken from the darkest and most likely to be infected spots. The first group of four buildings consisted of the main building (parlor, sitting-room, and public library); the infirmary where all the acutely sick are sent; the oldest cottage and the most recently built cottage. One square yard of dust from each of these buildings was collected and ten guinea-pigs inoculated with it. From each of the remaining thirteen cottages a half a square yard of dust was taken and three guinea-pigs inoculated. These inoculated animals were kept from one to three months and then killed and microscopically examined. Five were found to have had tuberculosis, four others having died on the third to sixth day of other infectious diseases. The five that had tuberculosis constituted just one-half of the number of pigs inoculated with dust from the oldest cottage on the grounds, accommodating two patients, always advanced cases, one of them having been complained of by his roommate for spitting around the cottage.

It was thus scientifically proven that in this case carelessness and disobedience of rules, which a weak and sickly man is prone to break, were responsible for the infection of a cottage, thereby rendering it dangerous to himself and others.

On the other hand, the remaining sixteen buildings, some of which had been occupied for ten years by consumptives, were absolutely free from infectious material.

Such, then, are the results in a sanitarium favorably located in the Adirondack Mountains, presided over by one who is giving the best years of his life to the scientific treatment of tuberculosis, at the bedside and in the laboratory.

But what may we expect to find in the city hospital, where clouds of dust sweep over us from we know not where, and smoke from factories and locomotives poison the atmosphere?

Cornet collected dust from the walls and headboards of beds in seven of the hospitals of Berlin where phthisical patients were treated, and inoculated ninety-four animals. Fifteen out of twenty-one rooms furnished tuberculous matter. Of the ninety-four animals fifty-two died of other diseases; of the remaining animals, killed after forty days, twenty were tuberculous and twenty-two were sound. Tests of dust from the walls of houses of fifty-three private patients affected with tuberculosis were introduced into 168 animals, of which ninety died soon after the injection, thirty-four were found tuberculous, and the remainder sound. In the aggregate about one-fifth of the animals submitted to these tests were found to have become tuberculous. If acute intercurrent disease could have been avoided the proportion no doubt would have been still greater, as many animals died of some acute infection within two or three days. Cornet found that in no case was the dust infectious when gathered from rooms where cups and cuspidors were used exclusively to receive the sputum. We have seen that here again Dr. Hance has corroborated Cornet's result.

Dr. Hance examined the dust from the wards of a large city hospital occupied by tuberculous patients of both sexes. Out of nine pigs inoculated, five died of acute infection within three days. The four living pigs were killed at the end of sixty days and one had well-advanced tuberculosis.

Nurses, as a class, are unquestionably very liable to contract phthisis, but I do not believe that in this country the liability is anything like what is said to exist in Europe. The religious orders throughout the continent supply nurses for most of the large hospitals, and it is no doubt true that close confinement in convents, and the subsequent hard work and exposure to disease, renders them an easy prey to tuberculosis. It has been said that an examination of the records for twenty-five of thirty-eight European nursing societies, sixty-two per cent. died of tuberculosis. These records gave the cause of death in four thousand of the members.

I do not know that anyone has made investigation of the causes of death among American nurses in general; it is an important subject for study. We have it, however, on the authority of Dr. Herman M. Biggs, that in one of the New York hospitals as many as eleven nurses and orderlies, previously healthy, had been dismissed within a little more than two years because suffering from tuberculosis. It was an overcrowded and poorly ventilated institution.

I think I have thus made plain that dust is the abomination to be shunned. We shall probably never live where we can absolutely avoid it, but we can do a great deal toward preventing its virulent character. If the doctrine of spontaneous generation had been established, little encouragement might be expected in a fight against infectious diseases, but, as Pasteur said, thirty years ago: "Man has it in his power to cause parasitic diseases to disappear off the surface of the globe." Prevention, like charity, properly begins at home; and eternal vigilance is the price of safety. We can point with pride to the perfection of neatness seen in this hospital. In the first place its situation is not so exposed as in the case of some institutions. Its construction with marble and hardwood floors, its staircases of marble and iron; its painted walls and ceilings; the use of steam radiators, and the best appliances which a liberal management can furnish, go far to insure a good return for the efforts made to preserve cleanliness and good order.

In our own homes few have marble floors and steam heat, and painted walls are not looked upon with favor. We can, however, make a warfare against dust. A hardwood floor is conducive to health, because it quickly shows

[1] *Archiv f. Med.*, Bd. xxix, S. 59.

the presence of dust or dirt, and can easily be kept clean. But, best of all, we have sunlight. The tubercle bacillus is one of those imps that loves darkness rather than light, because his deeds are evil. There is no disinfectant so potent against tubercle bacilli as bright sunlight. The sunniest spots are the safest. In choosing a home avoid shadows from trees or high buildings; avoid dampness, especially dampness of the soil, and above all make inquiry as to previous occupants, whether in your home or your hotel, and if tubercular disease has been present, and no proper disinfection or supervision of the patient has been practised, see to it that the quarters are put in proper order or secure others.

I commend to your perusal the three tracts issued by the Pennsylvania Society for the Prevention of Tuberculosis, entitled: "How to Avoid Contracting Tuberculosis," "How Persons Suffering with Tuberculosis can Avoid Giving it to Others," and "How Hotel-keepers can assist in Preventing the Spread of Tuberculosis."

CLINICAL MEMORANDUM.

TWO CASES OF ACUTE MASTOIDITIS IN PERSONS SUFFERING FROM DIABETES MELLITUS.

BY J. E. SHEPPARD, M.D.,
OF BROOKLYN, N. Y.;
PROFESSOR OF OTOLOGY, LONG ISLAND COLLEGE HOSPITAL, AND AT THE NEW YORK POLYCLINIC; AURAL SURGEON, BROOKLYN EYE AND EAR HOSPITAL.

IN a recent issue of the MEDICAL NEWS (March 21, 1896), Dr. R. A. Urquhart, of Baltimore, reports "Two Cases of Abscess in the Mastoid Region, Associated with Diabetes Mellitus," and says, in the course of his remarks thereon, "that there does seem especial tendency to inflammatory changes in the mastoid region in the dyscrasia under discussion, there is unmistakable evidence, but as to the existing relationship, we are as much in the dark, as we are ignorant of the true nature of the diabetic diathesis." In reading over these remarks, the question arose in my mind as to whether or not my own experience was in accord therewith. Out of a considerable number of cases of mastoiditis, two of them have occurred in diabetics, whose histories I will relate, and from them try to answer the above question.

CASE I.—Mrs. C., aged fifty, was referred to me by Dr. F. W. Wunderlich, and was first seen at her home, March 7, 1893. She gave this history: Discharge from the left ear eleven days, preceded by ten days of severe pain, which pain has only gradually subsided since the commencement of discharge, until it has now ceased. At first had a loud pulsating tinnitus, which has stopped. Has severe pain in the right ear ever since two days after the pain began in the left ear, but as yet no discharge; the pain has been, throughout, accompanied in this ear by a pulsating tinnitus. The undoubted cause of her trouble was snuffing salt water up the nose, which she had done at the suggestion of a neighboring druggist. H. D. w. R. p '60, L. p/60; wh. R. 30", L. 20". Right canal partially filled with oil, etc., and, after clearing this out, the membrane was seen to be very red, with considerable bulging of the posterior half. Left canal full of sero-pus; left membrane has a small, nearly central, perforation, through which the sero-pus is constantly exuding. For treatment, punctured at once the right membrane, letting out a large quantity of sero-pus; inflated, and ordered the hot douche used every two hours. During the following ten days she was, the early part of the time, quite comfortable; the last few days, however, was suffering considerable pain in the right half of the head, with continued discharge, renewed pulsating tinnitus, and beginning mastoid tenderness until, on March 17th, it seemed to me unsafe to longer postpone opening the mastoid. This was accordingly done. The mastoid was found made up of small cells, in many of which were unhealthy granulations and a near approach to, but not absolutely, pus; cleansed and dressed in the ordinary way. March 20th, the old pain has been quite relieved. There is to-day some infiltration, hard and tender, along the anterior border of right sterno-mastoid muscle. Learned to-day, for the first, that patient is a diabetic. March 27th, the infiltration has, during the past week, in spite of every effort to stop it, increased, and pus has formed underneath the muscle, which can be pressed out through a sinus connecting with the mastoid wound. As this condition was extending, a counter-opening was made along the anterior margin of the sterno-mastoid, about three inches below the mastoid wound, and a drainage tube inserted. For the two days following this, there was quite extensive irregular infiltration extending around under the chin, down the sterno-mastoid muscle, and over part of the sternum. As I was without previous experience in diabetic mastoids, it may be imagined I was somewhat aghast at this extensive infiltration. I do not even yet understand the *rationale* of its occurrence, except that I believe it was due in some way to the sugar in the blood and other tissues. However, by April 3d the infiltration had largely disappeared, except immediately around the drainage tube, which was removed six days later. From this time on, the most noteworthy thing in the history of the case is the extreme slowness of healing, the patient not being in fit condition for final discharge until July 10th, the left ear having in the meantime quite recovered.

CASE II.—Mr. M., aged fifty-eight, seen by me in consultation with Dr. H. M. Sloat, May 1, 1893, who told me the patient has been a diabetic for probably a year; that when he took charge of him two or three weeks ago there was about ten per cent. of sugar in the urine, and that since that time he had been on diet, with marked decrease of the sugar. The attack with his ear dates back three weeks, at which time he was suffering from influenza. There has been discharge from the left ear three weeks, preceded for one day by pain, which was only partially relieved by the appearance of discharge, and soon returned to its former severity, being always worse at night. There has been, throughout, a loud pulsating tinnitus. Left auricle looks the least bit pushed out from the head; in left canal, pus, and along the posterior wall, very near the membrane, is a small, reddened, very sensitive, bulged portion. Left membrane has a posterior

superior, pouting, "teat-like" perforation, through which pus exudes freely. Prompt operation was recommended, and performed the next day, May 2d. Immediately after the first incision to the bone and loosening up of the periosteum, considerable pus escaped, apparently from a necrotic perforation of the cortex, just at the outer posterior border of the bony canal wall. The outer cortex was then chiseled away, with the escape of a large quantity of pus, the cell divisions being largely necrotic. The antrum was freely opened and scraped out, cleansed, and packed as usual. As a result of experience with the preceding case, I determined to dress this case daily, which was done.

The patient had not an untoward symptom until May 13th, the discharge from the tympanic cavity having ceased, the perforation in the membrane having healed, and the patient was about to leave the house. On this day he commenced to have symptoms which, while at first not very definite, ultimated in an attack of erysipelas, only clearly recognizable, however, by May 17th. May 24th, the attack of erysipelas has proven to be a severe one, affecting the whole right side of face and head, with considerable sloughing of upper eyelid; temperature repeatedly 104°; pulse 112–120; at times drowsy, at times restless, with some delirium the last day or two. The wound has not seemed seriously affected by the process, except that the granulations became rather flabby and pale, and the healing process stopped. The dressings have been continued with the utmost care twice daily since the 10th.

May 27th, consultation with Drs. Fowler and McCorkle, who, after going over the case together, expressed the conviction that the operation had been in every way a success, and that nothing different was to be advised, so far as the wound was concerned. Dr. McCorkle discovered a slight pneumonic process posteriorly over right upper lobe, whether septic, hypostatic, or diabetic, was not decided, although it was thought to be probably septic. As the patient was rather growing worse, a consultation was had, May 31st, with Drs. Delafield and Gray, of New York. In their opinion, patient is suffering with purulent meningitis, "probably originating from the ear trouble, rather than from the erysipelas." June 1st, the patient passed an enormous quantity of urine, loaded with sugar, after which grew worse, and died June 5th.

The etiology of these two cases is quite clear—one due to snuffing salt water up the nose, the other due to influenza. Both of these causes are, as is well known, perfectly competent to produce mastoiditis in any one, whether a diabetic or not. I find I have histories of one hundred and seventy-five cases of affections of the mastoid. Considering that out of that whole number only two have, to my knowledge, occurred in diabetics, I believe that I am safe in answering that my individual experience does not coincide with the view expressed by Dr. Urquhart.

Dr. Buck related some cases, and drew some inferences from them, before the American Otological Society, at its last summer's meeting,[1] in which he brought up the much more important questions, in this connection, of prognosis, the necessity for, and the success from, operation. He concluded very positively that such cases should be operated upon, and that the prospect of success was fairly good. My reason for taking up this point is to refer to an incident in the history of the first case. When I found the patient had diabetes, I wondered very much that Dr. Wunderlich had not told me of the fact, and asked him the reason of his silence. He said he feared I would not operate, his reason being that, two or three years before, he had a similar case, which he had sent to a prominent specialist, who positively refused to operate on account of the diabetic complication, and the case had died, as Dr. W. felt, without a fair chance. My own belief is very strong that such cases should be operated, and the earlier the better.

Considering the prognosis from the light thrown upon it by these two patients, it seems to me proper to consider that we had three inflamed mastoids of the kind we are considering, of which one recovered without operation, one recovered by means of operation, and one died. In this last case, I certainly think it is an open question whether the infection of the meninges arose from the ear trouble, or from the erysipelas. The patient progressed perfectly satisfactorily until the eleventh day after the operation, and was about to take up gradually his usual active life, when the early symptoms of erysipelas manifested themselves; and it is my own positive belief that he would have recovered but for this unfortunate complication.

MEDICAL PROGRESS.

Rupture of the Heart in the Course of Rheumatic Ulcerative Endocarditis.—SAMGUINE (*Presse Médicale*, 1896, No. 15, p. 91) has reported the case of a man, nineteen years old, who for twelve days presented pains in the joints, and on examination was found to be suffering with acute rheumatism, without evidence of a cardiac lesion. In the course of six days the patient was seized with intense precordial pain, and on auscultation pericardial friction-sounds were heard, most pronounced at the base. At the end of three days the friction-sounds had subsided sufficiently to permit the feeble sounds of the heart to be heard in their purity. The precordial pain had disappeared and the temperature was but slightly elevated. Some articular pain persisted. On the following day, after a good night, the patient, on attempting to rise, fell back, pale and dyspneic, and in a few minutes was dead. Upon *post-mortem* examination about a quart of blood was found in the pericardial sac, the inner surface of which was shaggy with lymph. The myocardium was flabby and dull. Upon the posterior aspect of the left ventricle was an area of ulceration about three-quarters of an inch in diameter, at the lower portion of which was a small opening traversing the thickness of the myocardium. The orifice permitted the introduction of a little finger, and its borders were soft and friable. The valves of the heart were normal and the coronary arteries presented no atheroma. The kidneys and the spleen contained embolic abscesses, and there was besides incipient cirrhosis of the liver and chronic gastritis. The joints were hyperemic and contained synovial fluid, but no pus. Microscopic examination showed that at the site of perforation the myocardium

presented a round-cell infiltration and numerous small hemorrhages. In places only detritus remained. The adjacent myocardium was involved in reactive inflammation. In and around the blood-vessels at the area of ulceration were granulo-fatty matters and micrococci. The micro-organisms were present especially near the endocardial surface, and proved to be staphylococci cerei albi. Lesions like the one reported may result, it has been thought, from either extension of the ulcerative process of myocardium through the muscular wall of the heart, or by occlusion of a coronary artery (either from atheroma or through detritus and micrococci), with breaking down of the part of heart deprived of its blood supply. The latter is the more likely mode of occurrence. The accident is a rare one, occurring, according to Osler, but fifteen times among 209 cases of ulcerative endocarditis.

The Weight-Relations of Normal Puerpera.—As the result of a series of observations made at the Obstetrical Clinic of the University of Heidelberg, HEIL (*Archiv für Gynækologie*, B. li, H. 1, p. 19) found that the average loss of weight of one hundred puerperal women was five pounds for an average bodily weight of 122 pounds, about one to twenty-four. The greatest loss took place on the first day, gradually sinking to the fourth day, to ascend again on fifth and sixth days; on the seventh it approached that of the second and third. From the eighth to the tenth day the weight increased, to decline again from the eleventh. In eighty-two per cent. of the cases the minimum weight had been reached by the ninth day. In addition to the primary loss of weight in the first days of the puerperium, a secondary loss was appreciable, in the majority of cases, toward the close of the second week. In the case of women who did not nurse their children the loss of weight was below the average; as it was also in the case of unipara, tertipara, quartipara, and quintipara. In the case of deutipara the loss was above the average. The loss of weight bore a direct relation to the bodily weight. In young puerpera the loss of weight was strikingly slight. The loss of weight of a woman who had borne twins was thrice as much as the average loss in single deliveries.

THERAPEUTIC NOTES.

The Treatment of Dysmenorrhea.—TOUVENAINT (*Revue Internat. de Médecine et de Chirurgie*, 1896, No. 2, p. 39) divides the treatment of dysmenorrhea into symptomatic and curative. In the former he recommends the administration, several days before the expected time of the period, of emmenagogues, such as apiol, salicylic acid, cerium oxalate, and especially potassium permanganate (in doses of from three to nine grains daily). When menstruation has set in, a cataplasm containing tincture of opium may be applied to the hypogastrium, or an enema consisting of a glass of milk and ten or fifteen drops of tincture of opium is thrown into the bowel; or an enema of chloral is administered; or a suppository of the following constitution is employed:

R	Extract of opium . . .	$\frac{1}{3}$ grain
	Extract of belladonna . .	$\frac{1}{9}$ grain
	Cocoa-butter	45 grains;

or a hypodermic injection of morphin may be given. Four times daily the patient will take ten drops each of tincture of viburnum prunifolium and tincture of piscidia erythrina. Exalgin also may be tried in doses of from three to five grains, thrice daily. Cannabis indica has also proved serviceable, and from three to five drops of the tincture may be given every hour. In nervous women the bromids will be required, and a tablespoonful of the following may be given twice daily:

R	Strontium bromid. Ammonium bromid. Potassium bromid.	aa .	1½ drams
	Syrup of orange-peel . .		10 fluid drams.

Locally, frictions with a calmative liniment may be practised. Thus, take of

Oil of hyoscyamus . .		6 fluid ounces
Tincture of opium . .		1 fluid ounce
Camphor Extract of belladonna Mix.	aa .	1 dram

In the intermenstrual period, local and general applications of electricity may be employed. The general treatment consists in the electric bath, the static spark being applied to the lumbar region for twenty or thirty minutes. Locally, for the week preceding menstruation, faradization of the uterus is practised, and during the remainder of the interval, except in virgins, caustic effects are induced by the intra-uterine application of the cathode.

The curative treatment is surgical, and depends upon the causative condition. It will therefore require, in different cases, progressive dilatation of the cervix, followed or not by curettage and the introduction of a metallic stem (which is permitted to remain for a variable length of time) stomatoplasty, bilateral incision of the cervix, the correction of displacements, the enucleation of fibromata, etc. If conservative measures fail, and if the nervous symptoms persist, it may be necessary to undertake a radical operation, such as removal of the ovaries or vaginal hysterectomy.

Gonorrhœa of the Rectum in Women.—From a study of the records of the City Hospital of Frankfort-on-the-Main, BAER (*Deutsche medicinische Wochenschrift*, 1896, No. 8, p. 116) found that from June 15, 1895, to January 1, 1896, there were admitted to the dermatological department 296 women suffering with venereal diseases. Of this number 105 were syphilitic only, the remaining 191 presenting gonorrhœa, either additionally or exclusively. On careful and systematic examination of these 191 by means of a speculum, whether symptoms existed or not, Gonorrhœa of the rectum was found to exist in 67. In many cases the involvement of the rectum was unattended with special symptoms and objective manifestations. In others there was pain, redness, swelling, sometimes erosion, and discharge. In two cases periproctitis was a complication. The treatment consisted in irrigation of the rectum, once or oftener daily, at first with a three per cent. solution of boric acid, and subsequently with a 1–3000 solution of argentamin. Erosions were touched with a two per cent. solution of argentamin. In some of the latter cases suppository of ichthyol with cocoa-butter were used with satisfaction.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to The Medical News will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: J. RIDDLE GOFFE, M.D.,

SATURDAY, MAY 2, 1896.

AMERICAN MEDICAL ASSOCIATION—THE MEETING IN ATLANTA.

The meeting next week seems to offer a veritable feast of good things. The scientific department is well arranged, and the various sections are in good hands. With such leaders of thought as the president, Dr. Beverly Cole; Senn, in surgery; Osler, in general medicine, and Rohé, in hygiene, not to mention the other distinguished names that appear at the head of the various sections, the meeting is destined to be a memorable one. The general outings, in the way of by-excursions, are also attractive, and it is evident that the committee in charge can be depended on to fill the function of social host in a manner gratifying to the most exacting.

The concurrent meetings of the American Academy of Medicine, the Association of Medical Colleges, the Association of Medical Editors, and the Conference of the State Examining and Licensing Boards, is an additional interest of no little importance. As the *Journal* remarks, the former meeting in Atlanta, fifteen years ago, was a "history maker." Unless all signs fail the coming meeting will mark an epoch in the annals of the Association.

PUERPERAL SELF-INFECTION.

Obstetricians have been occupied during the recently passing years with problems of moment that have brought a new interest to obstetric science and art. Cæsarean section, being made elective, has been put upon the same basis as any other capital operation, with saving advantage to both mother and child. Symphyseotomy has been perfected in its aseptic technic and has taken its place among the accepted operative procedures before which no competent obstetrician hesitates when the indications are present. But brilliant and attractive as these procedures are, they pale into insignificance in comparison with the importance of determining the proper application of asepsis to the parturient woman, in the routine practice of the general practitioner. Cæsarean section and symphyseotomy are the exceptions; normal labor, when not interrupted or hastened by meddlesome interference, is of daily occurrence. What, then, shall be the routine practice regarding asepsis? Before this can be answered satisfactorily, it becomes necessary to look into the underlying principles or processes of infection.

The history of the evolution from the mysticism that surrounded the etiology of puerperal fever into the modern conception of puerperal septicemia is an interesting one; and it is gratifying to recall the debt obstetric science owes to the magic insight of Oliver Wendell Holmes, who first discovered the true nature of puerperal fever.

But obstetrics, like all surgical procedures, must take its teaching from the great principles of sepsis and asepsis. And the cardinal principles that have application here are two: (1) That all inflammatory processes, as indicated by rise of temperature, are of septic origin, and (2) that septic infection is by direct contact, and not atmospheric.

In obstetrics, an effort has been made to establish the principle of auto-infection to account for certain cases of puerperal sepsis, seemingly unaccountable according to the principles above enunciated, and this proposition was based upon the accepted fact that the vagina is the habitat of numberless bacteria. There remained for determination, however, the delicate question as to the virulence or innocuousness of these micro-

organisms and the properties of the vaginal secretions as a culture-medium or a germicide. Upon these two points hinges the entire question of self-infection. And here the students of the subject have ranged themselves in diametrically opposite positions. Dr. Charles Jewett set forth the status of the subject very clearly in his paper, read before the New York State Medical Society and reported in the Medical News of February 1st, and now appearing in full in the *Am. Gynec. and Obstet. Journal* for April. The extreme auto-infectionists maintain that pathogenic micro-organisms are always present in the vagina, and in condition to take on virulence when a favorable soil is provided by the decomposing discharges following labor. Every obstetrical patient, therefore is liable to infect herself. The opposing school maintain that pathogenic bacteria do not live in healthy vaginal mucus—indeed, that the normal secretion is fatal to them. This immunity, according to Döderlin, is due to the acid condition of the normal secretions, which acidity he attributes to an acid-producing bacillus. Jewett concludes that the findings of the bacteriologists tend to establish the belief that the vaginal secretion is infectious when diseased, and possibly so in health. But it is well not to forget that the findings of the bacteriologists require confirmation by the clinician.

In the clinical experience of prominent obstetricians, we find the practice which is based upon these extreme views of the bacteriologists, correspondingly at variance; one faction insisting that preliminary and *post-partum* antiseptic douches are indispensable, and the other claiming that such douches are not only useless, but harmful. The middle ground is doubtless the safe one; namely, that the healthy parturient, in the absence of contact infection, is safe against septic disease, and the routine douche is a useless and possibly injurious practice. But when the secretions are pathological, as shown by their alkaline or neutral reaction to litmus-paper test, and in doubtful cases, confirmed by culture test, thorough antiseptic cleansing is indicated and imperative. All this discussion presupposes the acceptance of the most thorough external subjective and objective asepsis on the part of the accoucheur, the nurse and the patient.

BACTERIOLOGY.

THE DETECTION OF TYPHOID BACILLI IN WATER AND IN FECES; ELSNER'S METHOD.

The usual increase in the number of typhoid fever cases in summer, especially in those occurring at summer resorts, naturally makes a consideration of the means which we now possess, for the detection of the typhoid bacilli, a timely one.

The greatest difficulty in identifying the typhoid bacillus in water and feces arises from its marked resemblance to the common colon bacillus.

It is true that the characteristic typhoid and colon bacilli differ in many important respects from each other, but on the other hand, some typhoid bacilli present many of the characteristics of the colon bacilli, and some colon bacilli those of the typhoid group. This resemblance is so marked that many have been led to suggest that they both belong to the same species, and that one would, under favorable conditions, change into the other. This view is, however, losing ground. The usual differential tests, such as the degree of motility, the number of flagella possessed by the suspected bacilli, the growth in gelatin, in milk, on potato, in media containing sugars and albumins, and their pathogenic action have sufficed, as a rule, to at least strongly indicate that a certain bacillus was either a typhoid or colon bacillus. These tests have not been considered sufficient, however, to absolutely identify them. During the past year, two new additional means have been suggested, which give promise of aiding us in obtaining both bacilli from fluids containing other bacteria, and in surely separating them, one from the other. One of these means, the injection of the suspected typhoid bacilli or colon bacilli into the abdomen of guinea-pigs, along with minute quantities of the serum of animals immunized to typhoid or colon cultures, was treated of last month. If the bacilli, injected with the typhoid serum, were typhoid bacilli, they soon died, leaving the animal unharmed; if, however, they were the colon bacilli they increased rapidly in number, killing the animals.

The specific bactericidal substances developed in animals by repeated injections of the living cultures by Pfeiffer, have since been obtained in suffi-

cient strength to exert their specific power outside the body, and experiments are being carried on to prove the reliability of the results obtained, by noting the specific bactericidal effect upon the bacilli when injected in a quantity of either the typhoid or colon serum kept in the test tube.

The other addition to our means of obtaining the typhoid bacilli from feces or water, and identifying them when obtained, has been furnished by Elsner.[1]

Attempts having failed to obtain typhoid bacilli in pure cultures from mixtures by animal inoculation or to find media in which the growth of the typhoid bacilli would be so increased as to outstrip all other bacteria, Elsner tried to solve the problem by seeking media in which all other bacteria than the typhoid would be more inhibited in their growth than the latter. He tried various media by eliminating or adding different substances before he arrived at one which gave him at least a very marked degree of success.

He made his media as follows: To half a kilogram of chopped potatoes he added one liter of water, and boiled for 1½ hours. After straining through a cloth, ten per cent. gelatin was added. This potato gelatin should have a degree of acidity, such that each 10 c.c. would require 2½ c.c. of a decinormal soda solution to neutralize it. Finally one per cent. iodide of potassium is added and the media is completed. If a stock is to be kept for future use, the potassium iodide should be withheld until shortly before it is to be used.

On this culture medium, nearly all bacteria except the typhoid and colon bacilli, either do not grow at all or are greatly inhibited. The colon bacilli still grow more quickly than the typhoid bacilli, but so differently, that the colonies of the two bacilli can be, as a rule, easily separated. At the end of twenty-four hours, when the gelatin plates are studied with a lens of slight magnification, the colon bacilli are found well developed, while the typhoid are hardly visible at all. At the end of forty-eight hours, the typhoid bacilli appear as small, very finely granular colonies, those of the colon bacilli being much larger, coarser, and more highly colored. The difference in appearance is mainly due to the greater rapidity of growth of the colon bacilli. On plates containing very abundant colonies, those of the colon bacilli may look just like those of the typhoid.

Elsner tried his test practically in separating thirty cultures of typhoid and colon bacilli, and in every case the results agreed with a parallel series, tested by Pfeiffer's bactericidal serum. He found that in water, purposely contaminated with the typhoid bacilli, he could obtain the bacilli when they were present in very small numbers. Thus he put a loop of typhoid bacilli with twenty loops of colon bacilli into two liters of river water. From this, after thoroughly shaking, he took one loopful and again placed it in two liters of fresh water. After shaking, he once again took a loopful and put it into a third two liters of water. From this last water, which represented a dilution of the original culture of 1 to 8000 millions, he obtained the typhoid bacilli. He further examined the stools of seventeen cases of typhoid fever and found the bacilli readily in fifteen. The other two were convalescent cases, in which the bacilli may have disappeared.

From a rather limited experience, I should judge that Elsner has given us a method for the detection of the typhoid bacilli, in suspected feces or water, of great value. By limiting or preventing the growth of most other bacteria, especially those which liquefy gelatin, it allows us to more successfully study the plate cultures, and by causing the differences in appearance of the typhoid and colon bacilli to become more marked, it aids us in separating them. That this method will alone suffice to positively identify the typhoid bacilli, seems to me improbable. Pfeiffer's bactericidal serum test may prove sufficient for this whenever the bacilli are virulent.

WM. H. PARK, M.D.

ECHOES AND NEWS.

A CERTAIN nervous condition, said to result from excessive use of the bicycle, has been termed the "vibratory habit." Sir Benjamin Ward Richardson has presented the subject before the Medical Society of London, and evidently considers it a disease.

THE Russian Committee of the International Medical Congress, which will be held in Moscow next year, has very courteously reconsidered its determination to exclude English from among the official languages of the meeting.

It is now decided that English will be placed upon the same footing as German and Russian in the reading and discussion of papers, but that French will be used in the transaction of all official business.

AT a meeting of the Philadelphia County Medical Society, held April 15th, a committee was appointed to urge the members of the American Medical Association to favor the holding of a semi-centennial celebration of its organization. The society also instructed its delegates to invite the association to hold the meeting of 1897, which will be the semi-centennial, in the City of Philadelphia.

DR. CHARLES W. STILES has recently received the high honor of being elected corresponding member on Medical Zoölogy of the French Academy of Medicine. Dr. Stiles, although only twenty-eight years of age, has been for the past five years zoölogist of the Bureau of Animal Industry in the U. S. Department of Agriculture, and is recognized as an authority in his particular branch of science.

A PHYSICIAN recently appeared at a medical society with a pocketful of spoons, which he had gathered during his professional rounds, with a view of measuring their capacity. He found them to vary from two-thirds to three times the standard capacity. One spoon held just five times as much as another of the collection. The practical application of these facts is obvious.

DR. SAMUEL HYDE of Buxton, England, writes to the *British Medical Journal* that he has had prepared an extract of fresh articular cartilages and synovial membranes from healthy animals, which he is trying as a therapeutic agent in cases of chronic joint diseases, including rheumatoid arthritis. The apparent analogy between the degenerative changes of the latter and those in other diseases in which animal extracts have proved beneficial, leads him to hope for favorable results in these obstinate affections.

THE RIVERSIDE ASSOCIATION in New York has established, under the direction of Dr. Simon Baruch, a system of baths for the purpose of enabling people in the most moderate circumstances to obtain the benefit of the water treatment. A dispensary practice is the severest test to which any therapeutic measure can be put, and it is proposed by this institution to apply the water treatment to chronic diseases which have resisted other methods. To this end the profession are invited to send any and all dispensary cases of intractable diseases to the Association House, No. 259 West Sixty-ninth street, daily between 2.30 and 4 P.M. The Riverside Association is a chartered body, organized according to the usual methods of dispensary associations, for the purpose of assisting the poor in many and varied directions.

TWO Parisian investigators have found the temperature of the normal human liver to be one degree centigrade higher than the intestines. The normal temperature of the other organs diminished in the following order: spleen, heart, kidneys, brain, muscles, and skin.

THE INSTITUTE PASTEUR, Paris, has just published its report for 1895. The salient feature of the statement appears to be that of 1523 persons treated only 5 succumbed to their injuries. In the fatal cases the symptoms of rabies manifested themselves within fifteen days after the first inoculation; one patient, however, was seized with rabies during the course of the treatment, and has not been included in the figures. A table of statistics contains the figures commencing from 1886, showing that of the 2671 persons treated in that year 25 died, or a mortality of .94 per cent., while in 1895, of the 1523 treated only 2 died, or a mortality of .13 per cent.

DR. ERNEST B. SANGREE of Philadelphia, has been elected professor of pathology and bacteriology in the Vanderbilt University, Nashville, Tenn. Dr. Sangree is at present pathologist to the Philadelphia Hospital, assistant professor of pathology in the Medico-Chirurgical College, adjunct professor of pathology in the Philadelphia Polyclinic, and member of the Academy of Natural Sciences.

THE announcement of the death of Count Mattei brings again to mind the investigation of the quackish methods of this eccentric impostor by a committee of English physicians. Unfortunately, this committee quarreled among themselves, and their report was incomplete. The late Count proposed to cure cancer with preparations of colored water, which he bottled and called electricities, and occasionally he resorted to inert powders for a like purpose.

A NOTABLE and most commendable interest in the study of the natural sciences by comparative methods has simultaneously developed in several American universities. A chair of comparative pathology has just been established in connection with the Medical Department of the University of Buffalo, which will be filled by Dr. Woods Hutchinson. This is the first of its kind in America, but is closely followed by a gift to Harvard of $100,000 from a wealthy merchant of Boston, to establish a similar chair in that institution. The holder of this professorship, who has not yet been selected, will be a member of the Medical School, and devote himself to the study of diseases of both men and animals, with reference to their relationship and cause, as well as to their cure and prevention. No more important indication of scientific progress has marked this last decade of the nineteenth century than this movement to encourage laboratory investigation.

MEDICAL women are now admitted to practise in Austria, under conditions requiring not only a high professional education, but also a blameless moral conduct. In certain provinces their services are in urgent demand for the care of many Mohammedan women, who have heretofore been without medical attention.

AFTER investigating the subject with the thoroughness characteristic of the continental scientists, Professor Wolffhügel of Göttingen, decides that burial in accordance with the general rules practised in America, is not unhygienic. However, the grave should not be opened for thirty years, although complete decomposition often occurs in six. Cremation cannot be considered as a *sine qua non* in ideal sanitation. While discussing this gruesome subject it may be well to mention that a French physician has recently written a book upon the bacteria of dead bodies,

showing that different varieties are present at the several stages of decomposition. In medico-legal practice, it may be of value to thus determine the time that has elapsed since death, which this author claims may be easily done by a study of the "fauna of the cadaver."

Microbes in milk was the subject of a paper recently presented before the Edinburgh Royal Society. It was found that in winter 24,000 bacteria were the average for each cubic centimeter, and 173,000 in late summer and autumn. Milk from country dairies was found to contain an average of 44,000, while that from cows confined in town averaged 352,000 per cubic centimeter. It was not urged that any or all of these were necessarily virulent. This field should receive thorough attention from our bacteriological laboratories, not only to determine when milk is unfit for food and methods for its sterilization, but also to acquaint the dairymen with the scientific methods of successful butter-making, which is more or less dependent upon the presence of micro-organisms. It is not impossible that discoveries more valuable than those of Pasteur in the process of brewing, may be made in this industry.

Under authority of the statutes relating to food and drug inspection, the State Board of Health has examined such samples of diphtheria antitoxin as are offered for sale in Massachusetts, with the following results:

Serum No. 2, Behring. Bottle containing ten cubic centimeters of serum of an advertised strength of 1000 units.

The test showed that the serum was up to the standard.

Serum of Parke, Davis & Co. Bottle guaranteed to contain ten cubic centimeters of a total strength of 1000 units.

The test showed that the serum was up to the standard.

Serum No. 2, of Mulford & Co. The label states that the bottle contains ten cubic centimeters of a total strength of 1000 units.

The test confirmed the statement, and showed the serum to be up to the guaranteed strength.

Serum of the Pasteur Institute of Paris, France (Roux). The circular states that the serum is at least 1–50,000 in strength. As this is considered equivalent to Behring's serum No. 1, the test was carried out with this strength in view. It was, however, found to be weaker than this. A second test showed that the ten cubic centimeters of serum contained a total of 500 antitoxic units, instead of 600 units.

Gibier's diphtheria antitoxin, New York. The label states that the bottle contains twenty-five cubic centimeters, of a total strength of 2500 units. The test showed that the serum was far below this in strength. In a second test, it was determined that the bottle contained from 625 to 750 units, instead of 2500, as advertised. The strength of this serum is thus a trifle below one-half of that of Behring's serum No. 1; ten cubic centimeters of Behring's serum No. 1 contain 600 units.

We understand that the samples were obtained directly from the producers or their agents.—*The Boston Medical and Surgical Journal.*

CORRESPONDENCE.

To the Editor of the Medical News:

Dear Sir: I have before me a reprint entitled "A New and Rapid Method of Dealing with Intra-ligamentary Fibromyomata," by Dr. W. R. Pryor of New York (Medical News, December 1, 1894), and in justice to Dr. Pryor's original and valuable work in this field, I desire to yield him the credit of using a plan of dealing with intra-ligamentary tumors, in all important particulars, similar to that which I have been using and demonstrating at my clinics at the Johns Hopkins Hospital for a year and a half past (*Johns Hopk. Hosp. Bull.*, February and March, 1896). Dr. Pryor's publication and use of the operation in this important part of the field, antedates my own, and would have received full credit if I had seen it.

He describes very graphically the removal of an intra-ligamentary tumor, and dwells fully upon the great advantage of this way of dealing with them.

He makes also a suggestion, I think, of considerable value, in tying the ovarian vessels on the side last enucleated before tying the uterine vessels.

In my own work, I have almost exclusively adopted a supra-vaginal amputation of the cervix, and I perform hysterectomy in this way for all sorts of myomata as well as for pelvic inflammatory diseases, where drainage cannot be used. If I recollect, the evolution of this operation in my clinic, the design was at first for the rapid enucleation of ordinary myomatous uteri, and the advantages now apparent in the intra-ligamentary forms, were not perceived until a number of other cases had been operated upon. Yours truly,

Howard A. Kelly.

Baltimore, Md., April 27, 1896.

SOCIETY PROCEEDINGS.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, April 20, 1896.

The President, Joseph E. Janvrin, M.D., in the chair.

Dr. Louis Lichtschein read a paper on

HYPNOTISM AS A THERAPEUTIC AGENT; ILLUSTRATED.

He said that there was a diversity of opinion as to the correct theory of hypnotism, and that the estimates which different observers formed as to its therapeutic value were largely dependent on the theories which they accepted in regard to the subject. Charcot, to whom the profession was principally indebted for the modern interest in the study of hypnotism, contended that it is an artificial neurosis which can be produced in hysterical persons only. In his view, therefore, its domain was very narrow and the dangers attending it were very great on account of its liability to do serious injury to the nervous system. On the other hand, the Nancy school of hypnotists, headed by Liebault and Bernheim, advocated the theory of simple suggestion, and held that hypnotism was nothing else but persuasion.

Charcot professed to observe three stages: (1) catalepsy, (2) lethargy, and (3) somnambulism; but the truth is that no one outside of Salpétrière had been able to recognize these three stages. The question arose: Are hypnotism and hysteria always associated? which must be answered in the negative. On the contrary, the more sound a brain is, as Forel had shown, the more easily is it affected. The school of Nancy held that every person is more or less susceptible, and Bernheim discriminated no less than nine degrees of hypnotic influence, beginning with somnolence and ending with post-hypnotic, retro-active hallucination. The main point contended for is that there is no hypnotism that is not suggestion. Suggestion, as defined by Bernheim, is an idea which is introduced into the brain and is accepted by it.

After some explanations as to the probable *modus operandi*, in which hypnotism produced its effects, Dr. Lichtschein proceeded to speak of its practical value as a therapeutic agent. In diseases like cancer, tuberculosis, syphilis, etc., when there were serious structural changes, no benefit, he said, could be expected from it. Hynotism was by no means a panacea, but there were many acute and chronic diseases in which suggestion might act in a curative manner. A number of these he referred to. Functional nervous diseases of various kinds were among those most amenable to it. In neurasthenia, however, it was difficult to obtain good results; but with patience and perseverance these could usually be finally arrived at, though considerable time might elapse before a cure was effected. The same was true in regard to hysteria, and hystero-epilepsy. True epilepsy was not affected by it. In facial paralysis, associated with hemiplegia, he had some satisfactory results. Suggestion was a very valuable agent in the treatment of alcoholism, and whatever efficacy there might be in the so-called Keeley cure was no doubt due to this cause. In the morphia habit its application was more difficult, but much could be hoped from it with proper care. In three out of the four cases that he had personally cured he had found it necessary to induce uninterrupted sleep for from ten to twenty days. The chloral habit could also be overcome by it. Hypnotism was of special value in the treatment of nervous asthma, and of neuralgias, especially of the fifth nerve. The peristaltic movements of the intestines could be controlled by it in a remarkable manner, and both diarrhea and chronic constipation (when not due to fermentation) could be cured by it. In anomalies of menstruation, such as profuse menorrhagia, due to mental conditions, it was also of great value. One of the most useful fields in its application was found in masturation and satyriasis, and here it really acted as a specific. In the various forms of perverted sexual appetite, however, it did not offer such good results. In enuresis, by night or day, it was a useful remedy, though it required considerable patience to effect a complete cure.

Dr. Lichtschein thought that no harm could result from the judicious use of hypnotism. In the hands of the inexperienced, however, he believed that it was capable of producing serious injury, as it might cause a shock to the nerves which might eventually unbalance the nervous system. It should be used solely for its therapeutic effect, and only in the way of gentle persuasion. Therefore its practice by lay operators and in public exhibitions should be prohibited by law, as was now the case in Europe and in some of our Western States. He then gave a summary of five cases of different kinds which he had selected from those in which he had effected cures by this agent. In conclusion, he illustrated the various stages of hypnotic influence by means of two trained subjects, a male and a female. In the male the lower degrees were demonstrated, and in the female the higher degrees.

DISCUSSION.

DR. H. ERNEST SCHMID of White Plains, who was present by invitation, said that since he presented his paper on hypnotism before the State Medical Association, five years ago, he had paid much more attention to the psychical phenomena connected with it than to the practical bearings of the subject. As a result of his investigations, he was entirely opposed to the views of Charcot, and accepted those of Bernheim and Liebault. In his opinion, suggestion was the grand factor in the production of the results noted, and not hypnotism itself. He agreed with the reader of the paper that epilepsy had never been influenced by hypnotism. The cases in which cures were reported from it he believed were always instances of hysterical convulsions. He also agreed with Dr. Lichtschein that whatever benefit there was in the Keeley treatment was due purely to suggestion. During the past year or two strenuous efforts had been made to induce the legislatures of Massachusetts and Connecticut to force the medical authorities of the insane and inebriate asylums of those States to introduce this charlatan system into the institutions under their care; but as yet this outrage had not been consummated. It was certainly a curious fact that the State of Massachusetts, with all its boasted enlightenment, should be the first to bring up a bill in favor of charlatanism. The man of all others, he thought, who had been most successful in elucidating the *modus operandi* of hypnotism was Thomas J. Hudson. His idea was that there were two minds, an objective one and a subjective one. The one acted through the five senses, and the other acted by intuition. In this way every act of suggestion could be best explained, the objective mind operating on the subjective mind.

DR. WM. M. LESZYNSKY said it was evident, from the large audience present, that hypnotism had not lost its popularity, even among members of the medical profession. He had come expecting to hear the subject treated in a different manner, and hoped to find that the reader of the paper would say something in regard to the injurious effects of hypnotism. He was willing to concede that this agent had a beneficial influence in a small number of cases seen by neurologists, as, for instance, in some cases of neuralgia, but it was only in a small number. Even in its milder forms, it sometimes acted injuriously, and he had met with a number of such instances. One of these, in the case of a young girl suffering from classical hysteria, he related. Dr. Lichtschein had made the statement early

in his paper that it was not a universal panacea, and yet afterward he had appeared to claim that it really did cure almost everything. In neurasthenia, indeed, he had admitted that the cure took a long time. But in this affection almost any kind of treatment took a long time, and it might well be questioned to what extent any improvement noted was really due to hypnotism. As to facial paralysis accompanying hemiplegia, as the one was due to the same cause as the other, viz.: an organic lesion in the brain, he failed to see how this treatment could benefit one trouble, and yet not affect the other. In insomnia suggestion was no doubt of great value, and the fact was that herein we all practised suggestion on ourselves.

He had no wish to ridicule hypnotism. It was an interesting reality, although we did not as yet understand its phenomena very clearly. Nothing had been shown here to-night which threw any light upon the subject from a scientific point of view. We had all seen such demonstrations over and over again, and, although admitting the honesty of the trained subjects and the good faith of the operator, they proved nothing. All were satisfied, however, that hypnotism has its sphere in therapeutics; but, in his opinion, it was a remedy which could be used in only a few well-selected cases. He did not think that we were justified in making the attempt to hypnotize different patients to see whether they were susceptible to its influence or not. There were, indeed, many persons who, even under the most favorable conditions, could not be hypnotized at all.

In closing the discussion Dr. Lichtschein said that he agreed with Dr. Schmid that epilepsy could not be cured by hypnotism, notwithstanding the claims that had been made by some observers in regard to this point. As to the Keeley treatment, it was simply an abortive attempt at suggestion. The rest of his remarks were devoted to a reply to some of the criticisms made by Dr. Leszynsky.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, April 22, 1896.

The president, Dr. J. C. WILSON, in the chair.

DR. H. A. HARE reported a group of interesting cases. The first was one in which occurred attacks of epileptiform character, that were controlled by a regulation of the diet and the administration of antiseptic and purgative drugs. The second was in a boy, nineteen years old, who suffered from symptoms of digestive derangement and presented rhythmic contraction of both recti abdominis muscles on manipulation of the abdomen. Examination of the gastric contents disclosed the existence of gastric catarrh, with fermentation; and relief of all the symptoms followed lavage and regulation of the diet. The third case was in a boy of nineteen, with aortic obstruction, who presented signs of general peritonitis, with some symptoms suggestive of appendicitis. Operation was undertaken, the incision being made in the median line of the abdomen. The ileum was found obstructed by a band of adhesion, and the appendix inflamed and also adherent. Evidences of general peritonitis were present. The appendix was removed and drainage provided for. When the tube was removed at the end of thirty-six hours, vomiting and other distressing symptoms returned, to disappear upon the introduction of gauze packing. During convalescence, and for some time afterward, the patient suffered from attacks of vomiting and other symptoms suggestive of intestinal obstruction, but improvement usually followed upon regulation of the diet. The fourth case was one of typhoid fever in a man twenty-three years old, in whom a relapse followed the giving of broth and rice after the temperature had been normal for nearly three days.

In conclusion, Dr. Hare added that it was common in his experience with typhoid fever for either recrudescences or relapses to follow the too early ingestion of solid or semi-solid food. It would seem as though the change from a milk diet to other form of food, favored in some way renewed activity on the part of the typhoid, and perhaps other intestinal bacteria.

By invitation of the board of directors, DR. HORACE G. MCCORMICK of Williamsport read a paper entitled

"SOME OF THE THERAPEUTIC USES OF GUAIACOL."

He related that during the past two or three years he has employed topical applications of guaiacol in the treatment of forty-three cases of typhoid fever, in hospitals and private practice, equally divided between the two sexes, and covering wide variations in age. In all, 864 applications were made, the largest number in any one case being 78, the smallest 1; the largest dose was 25 drops, the smallest two. The greatest reduction in temperature was from 108.6° to 101°, with a corresponding reduction in pulse and respiratory frequency. Dr. McCormick has not found guaiacol, employed topically, depressing; on the contrary, with the reduction of temperature, the drug seemed to have a stimulating influence upon a weak heart. One case, that failed to yield to the ice-pack, continued for twelve hours, responded at once to guaiacol. The reduction of temperature effected lasts from three to four hours. At first chills occurred, but these were noted less frequently as experience taught the smallest dose necessary for the antipyretic effect. The applications were usually made in the right iliac fossa, the skin being washed with soap and water, then dried thoroughly, the guaiacol finally being dropped on the surface and gently rubbed in for ten or fifteen minutes. The part was finally covered with oil-silk or wax-paper. In a few cases local irritation resulted from the applications. Otherwise there were no unpleasant effects. Sweating occurred nearly always, and was proportionate to the reduction of temperature. In a case of pyemia with a temperature of 107°, repeated applications failed to bring about a reduction. It was admitted that the pyrexia of typhoid fever is not the disease, but it is an important symptom, and, when pronounced, it demands amelioration. The cold bath is also an efficient means of treating typhoid fever, but guaiacol has the advantage of ease and practicability of application, accessibility, inexpensiveness, freedom from contra-indications and bad effects, and of not arousing the objections of patients and their families. Guaiacol may also be used internally as an intestinal antiseptic, but thus employed, it does not reduce temperature. In cases of typhoid fever, such use is followed by a lessening of tympanites,

moistening of the tongue, and subsidence of delirium. The drug has been given in emulsion and in capsules, but its taste is disagreeable, and guaiacol carbonate may be given instead, in doses of 2½ grains.

Dr. J. V. Shoemaker stated that he had employed guaiacol, especially in the treatment of such diseases of the skin in which, formerly, it had been the custom to employ creosote and carbolic acid, *e.g.*, superficial epitheliomata, lupus vulgaris, and old ulcers. The remedy has also been employed topically, with success, in the treatment of orchitis and epididymitis.

Dr. H. A. Hare pointed out that guaiacol possesses pretty much the same powers and dangers as the coal-tar antipyretics—antipyrin, acetanilid, phenacetin, etc. It is, however, not so useful as the cold bath, intelligently applied. It must be remembered that fever has some protective influence, and may be viewed as the reaction of the organism to the invasion of the disease process. The cold bath does more than reduce temperature. It has, besides, a distinctly vitalizing influence, stimulating in general the functional activities of the organism. Dr. Hare criticised the routine employment of the cold bath, and maintained that this procedure is not to be pursued in every case, but only when other measures prove insufficient. The question is essentially one of dosage, and it is necessary to adapt the treatment to the disease as seen in individual cases.

Dr. J. P. C. Griffith contended that it was not possible to properly control the action of guaiacol applied topically as an antipyretic. It is difficult, if at all possible, to determine in advance how many drops of the remedy will be necessary to effect a given reduction in temperature. Experience shows the decline to be too great.

Dr. J. M. Anders related that, in an extensive experience with guaiacol, he had twice observed its application to be followed by a rise to a point higher than the previous maximum temperature. He had therefore abandoned its use in cases of typhoid fever, and had confined its employment to cases of subfebrile and afebrile disorders. Thus the drug had yielded good results in the treatment of myalgias and neuralgic pains. For this purpose, it was mixed with an equal part of glycerin and painted upon the affected surface. Dr. Anders has found that the hypodermic use of the drug proved even more effective than the topical application, a minim or two of guaiacol being mixed with ten minims of chloroform, and the dose repeated as needed.

Dr. Frank Woodbury pointed out that the action of guaiacol is probably to be attributed to its absorption into the blood and its influence on the thermic centers. Guaiacol has also proved itself useful in the treatment of pulmonary tuberculosis. It constitutes about sixty per cent. of creosote, which is the best single agent at present known in the treatment of tuberculosis. Carbolic acid and guaiacol do not act alike; the former is far more toxic. On account of its disagreeable taste, guaiacol has been superseded for internal administration by guaiacol carbonate. Under this plan of treatment, it has been observed that hectic is reduced and retrograde changes effected in the morbid process in the lungs.

Dr. S. Solis-Cohen stated that he had had an opportunity of seeing some of Dr. McCormick's cases, and had come to the conclusion that the patients had passed through a dangerous disease as safely and as comfortably as after any other mode of treatment. Nevertheless, he was unable to agree that the drug should supersede the cold bath. Briefly stated, it is an excellent means of treatment in suitable cases. Guaiacol, internally, is, like salol, an excellent antiseptic, and is capable of controlling the fetor of the stools. For this purpose, the carbonate and the salicylate may also be used. It is a fair question whether the reduction of the temperature in cases of pulmonary tuberculosis by means of applications of guaiacol really does good, and whether the patient is better off for it. The reduction is not permanent, and the applications, to be effective, must be repeated frequently. The matter of personal idiosyncrasy must be taken into consideration, some individuals reacting to a moderate dose, while in others a large dose induces but a slight effect. Applications of guaiacol seem to prevent the growth of the diphtheria bacillus in the throat. Dr. Cohen referred to two epidemics of diphtheria at the Pennsylvania Training School for Feeble-minded Children at Elwyn, in which the outbreak was brought to a close by the topical application to the throats of the healthy children of guaiacol, diluted with fifty per cent. of sterilized olive oil, with the addition of ten per cent. of menthol.

Dr. McCormick, in conclusion, replied that he had not observed any increased elevation of temperature after topical applications of guaiacol. The drug is, of course, not without its dangers, as all active medicaments are, but in the hands of the intelligent physician, these are minimal. Whether the application shall be made or not, must be determined in every individual case from the symptoms and general condition. Dr. McCormick repeated that while the fever is not the disease it must at times be treated, whether guaiacol or the cold bath, or other means are used for the purpose.

Dr. Joseph Price read a paper entitled

"RECTO-VAGINAL ANASTOMOSIS AND COMPLETE EXTIRPATION OF THE VERMIFORM APPENDIX."

The thought had suggested itself to him that in some cases of malignant disease of the uterus, with involvement of the bowel and adjacent parts, in which abnormal communications between the viscera are likely to occur, a cleaner and more radical procedure would consist in extirpation of the uterus and intestine, with the establishment of an anastomosis between the bowel and the vagina. He reported the case in which the hysterectomy was effected by the anterior method, incising anteriorly and retracting the bladder, opening the anterior vesico-vaginal pouch and tying backward. After completing the hysterectomy and amputating the diseased bowel, the proximal extremity of the intestine was stitched to the upper extremity of the vagina. The patient made an easy recovery with daily evacuations of the bowels after the fourth day. Dr. Price proposed also, in suitable cases, extirpation of the diseased appendix, cutting the organ out of the head of the cecum, and closing the incised opening with sutures. The operation has proved successful in a number of cases.

THE MEDICAL NEWS.
A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXVIII. NEW YORK, SATURDAY, MAY 9, 1896. NO. 19.

ABSTRACTS OF ADDRESSES DELIVERED BEFORE THE AMERICAN MEDICAL ASSOCIATION, ATLANTA, GA., MAY 5, 6 AND 7, 1896.

ADDRESS OF THE PRESIDENT, R. BEVERLY COLE, M.D., OF SAN FRANCISCO.

AFTER a general introduction of historical character, Dr. Cole stated that the American Medical College Association, had within the past two years brought about great changes in the desired direction of higher education. It must, however, be admitted that improvement had been effected but very slowly, and that the usage of many of the schools to evade the laws established by the Association is so general that the good result is small, and the manifest reluctance of so many now within the organization to embrace the last advance, namely, the adoption of the four years' requirement, gives but little promise for the future. Just so long as the examinations for matriculation are conducted by members of the faculty of medical schools, just so long will evils continue, and so long as the professional examinations for degrees are conducted by interested parties, just so long will the ranks of the noblest profession be filled with uneducated, untrained, so-called doctors.

Relative to making examinations for life insurance companies, he said that no man qualified to make a thorough examination, such as is required by insurance companies, if he be properly imbued with the value and importance of his services, will, or can assume the responsibility attaching to his function as an examiner without an adequate return. Surely the fee of five dollars was small enough, and the offer of any less sum is simply an insult to the educated physician, and a bid for cheap, unscientific service, which can be obtained from the ranks of the unskilled and irresponsible. Let every examiner plant his foot firmly and decline employment without adequate compensation; let it be published to the world that certain companies employ incompetent men, or by paying cut fees receive cut services, and very soon they will discover their mistake and be brought to the realization that the best and most skilful services command the best prices.

Another question of grave importance and to which he thought the Association should take cognizance and suggest a remedy, was the total absence of reciprocity between the United States and foreign countries as to laws governing the right to practise. Why Americans should be required, when taking up their abode in Germany, Great Britain, and even in the territory of our first cousin, Canada, to undergo an examination preliminary to securing a license, while our portals are floodgates through which every country of the earth pours its surplus of medical men, or rather, to put it more correctly, why our country should receive with open arms, without hindrance, the excess of product of foreign schools without requiring of them the same as is required of us, he could not see, and he was distinctly of the opinion that the time had arrived when the matter should be earnestly considered and something done to arrest the strides of this rapidly growing wrong.

He had noticed with inexpressible pleasure, the action taken by the Association at its last meeting, together with the hearty support at the hands of of the State Society of Pennsylvania, so far as the advertising columns of the *Journal* are concerned. In this case the reform commenced at home, and Dr. Cole said we should carry it further and apply it to individuals.

Equally gratifying is the effort now being made asking Congress for an additional member of the cabinet, who shall be known as the Secretary of Public Health, and who shall be head of a department to be known as the Bureau of Health, which will have general charge of health matters as well as statistics. Such a department would be of incalculable utility and value, and the measure should by all means possible be vigorously pushed forward.

While the year just passed had been marked by several important discoveries of scientific value, the usual advance in the line of medicine and surgery had been made, but he feared that the tendency to push surgery to the exclusion or

neglect of medicine, was becoming glaringly conspicuous. It would seem every tyro imagines that surgery offers the quickest route to success, and that fame is to be attained only through blood; hence every case, the symptoms of which are directed to McBurney's point, was necessarily a case of appendicitis, for which the only sovereign remedy was the knife; or if it be a woman, and her suffering is referred to the ovarian region, or she has a fibroma, very small and barren of symptoms of importance, not only must she be subjected to celiotomy at once, but in nine cases out of ten, is her uterus, or uterus and ovaries, sacrificed, thus unsexing her without the slightest effort being made to spare these organs and preserve to the woman her distinguishing function. If the same practice prevailed to emasculate every man who might have a neurosis of the cord and neighboring organs, there would be fewer operations than are now done on women for no greater cause.

The mere fact that the improvements and advancements in surgical procedures make them relatively safe, should not be advanced as an argument, and he looked with suspicion upon the surgeon who might claim that as no use can be assigned to the appendix vermiformis, it should, upon the slightest provocation or excuse, be removed. Is it not time that a halt should be called, and that such cases should be assigned to those who are expert in diagnostic technic as well as surgical procedures? Can any law of either God or man be found to justify oophorectomy or hysterectomy except under the most dire conditions?

ADDRESS ON MEDICINE,
BY WILLIAM OSLER, M.D.,
OF BALTIMORE, MD.

THE STUDY OF THE FEVERS OF THE SOUTH

[BY TELEGRAPH.]

HUMANITY has but three great enemies: fever, famine, and war, of which by far the greatest, by far the most terrible, is fever. It is worthy of comment that three of the greatest benefits conferred on mankind, beside which it would be hard to name three of equal importance, have been in connection with the fevers, the introduction of cinchona, the discovery of vaccination, and the announcement of the principle of asepsis. The differentiation of special forms of the continued fevers, and particularly that of typhoid, forms one of the most interesting chapters in medicine.

It is a very gratifying sign to notice the attention which has been given of late to the subject of typhoid fever in the South. Some years ago a good many physicians resented the imputation that the disease, to any extent, prevailed in the Gulf States.

I have been in the habit for several years of reading the reports of the discussions on this subject at the New Orleans Parish Medical Society, and they had been interesting as showing a progressive development of knowledge such as comes to all of us with fuller study of any problem. Enteric fever presents no constant picture. On the contrary, scarcely any disease has a more varied symptomatology. The fever may be said to be invariable, though afebrile cases are not unknown; but in the features of onset, in the length of its course, in the presence or absence of symptoms regarded as cardinal, such as rose spots, diarrhea and splenic enlargement, typhoid fever is so uncertain that the diagnosis is often dubious.

Advances in the treatment of fevers and especially of typhoid, have not kept pace with the rapid progress in our knowledge of the etiology. Think of the misery, the tediousness, the discomfort of a typhoid case with three relapses; think of the bleeding, the blistering, the purging, from which at least our fever patients of to-day are free. Contrast with the former methods the care, the gentle nursing, the scrupulous cleanliness, the abundance of cold water to drink, and fresh air which typhoid fever patients of to-day receive. I would claim the privilege of a faddist to abuse roundly other faddists who did not swim in my puddle.

As a strong advocate of hydrotherapy, I take especial pleasure in denouncing as heretics of the worst possible stamp the advocates of the so-called antiseptic and abortive methods of treatment of typhoid fever. I would place the man who does not also give a purge, in a limbo just a little less hot, as he probably does a little less harm. Scarcely a week passes in which I do not receive a temperature chart of some case of typhoid fever which has terminated spontaneously on the twelfth or fourteenth day, as a triumphant demonstration of the value of drugs, which, from my point of view, might as well have been given *per cutem* in the tub. At present, I am, however, so wholly opposed to cold water practices that I confess to be anything but an impartial critic. The advocates in this country for the abortive and antiseptic plan of treatment must bring forward a much stronger body of evidence than has been presented before they can hope to carry conviction to the skeptical. To claim an abortive treatment of typhoid in a case in which, on the

thirteenth day of the illness and on the seventh of the treatment, a patient died of intussusception as "cured of his typhoid fever on the seventh day of treatment," when the autopsy showed "the characteristic and extensive ulceration of Peyer's patches and tumefied mesenteric glands," is to talk a language unintelligible to an educated medical man, and is nothing short of midsummer madness.

Full clinical histories should be furnished of typhoid fever cases, and any one who wishes to contribute to the subject should not be too busy, not only to make a careful, critical study of the symptoms, but to jot them down in some order so that at least they may be intelligible to others. The second point is the necessity of obtaining autopsies in fatal cases. We all appreciate how difficult this is in private practice, but in determining the nature of obscure atypical cases of fever, it is absolutely essential. There is not a hospital in the country in which the determination of the nature of an obscure case of fever is not settled by the autopsy alone. Thirdly, it is essential that observers who undertake to study this question with thoroughness should approach it with a full acquaintance with the varieties of the malarial parasites, and with an accurate knowledge of bacteriological technic.

To us, as a profession, belongs the chief glory of the century. Enormous as has been the advancement in material prosperity, and widespread as has been the diffusion of benefits from the development of the physical sciences, they cannot compare with the progress which has been made in the relief of suffering and in the prevention of disease. Our work here ranks among the most memorable achievements in the history of the race. Fever in its various forms is still with us, and the century has seen in connection with it but one discovery of the first magnitude, but it is of almost equal importance to know that the way has been opened and that the united efforts of many workers in many lands are day by day disarming this great enemy of the race.

ADDRESS ON SURGERY,
BY NICHOLAS SENN, M.D.,
OF CHICAGO.

SOME OF THE LIMITS OF THE ART OF SURGERY.

Modern Surgery has attained a degree of development which entitles it to the distinction of a science and an art. As a science, surgery is of recent date, having been founded and perfected during the last half of the present century. As an art it has been practised for centuries by our ancestors, with credit to themselves and benefit to the injured, the crippled, and the sick. When Boyer wrote the introduction to his classic work on surgery he expressed the conviction that surgery had reached perfection. How little did he dream of the great changes that would be wrought in the practice of his cherished profession by the progressive pathologists and surgeons of the next few generations. What a contrast between the standing of the surgeon of to-day in the community, the profession, and, from a scientific aspect, as compared with his colleagues of only a century ago!

Modern pathology and the new science of bacteriology have laid a permanent foundation for the steady and progressive advance of surgical thought and work. The inflammatory complications of wounds and the etiology of most of the chronic infective surgical diseases have been cleared up by bacteriologic investigations during the last twenty-five years, and the knowledge thus gained has enabled the surgeon to prevent, in a large measure, the former, and to treat intelligently, and with increased success, the latter. The wonderful development of operative surgery, during the same time, is one of the earliest and richest fruits reaped from the vast and fertile field sown and cultivated by bacteriologists of every civilized nation. Antiseptic and aseptic surgery have smoothed the rough and rugged pathway of the practical surgeon.

The almost universal introduction of antiseptic and aseptic precautions in the treatment of wounds in private and hospital practice has nearly eradicated the three greatest enemies of the surgeon of old, namely, hospital gangrene, erysipelas, and secondary hemorrhage, and minimized the occurrence of suppuration and its manifold immediate and remote complications.

The *furor operativus* manifested in special departments of surgery, and its obvious results, render the standing and legitimate scope of the general surgeon very uncertain and indefinite at the present time. Let the general surgeon turn to the right or to the left, advance or retreat, and he finds himself on reserved territory. As for the physician, he is expected to answer night-calls, prescribe for diarrhea and whooping-cough, watch cases of typhoid fever, measles, scarlatina, and smallpox, and should complications arise, and he does not report to the proper authority, he renders himself liable to censure. Much of this ill-applied energy in the surgical world has resulted in detri-

ment to patients and in retarding actual surgical progress. Operative surgery has been carried to extremes.

The employment of antiseptic and aseptic precautions in the treatment of intestinal and accidental wounds has greatly diminished the frequency of progressive phlegmonous inflammation and its often disastrous consequences. That such an occurrence cannot always be prevented, even by the most scrupulous care and attention to details, every surgeon of experience is willing to admit. In the most virulent forms of phlegmonous inflammation the most heroic and timely treatment, local and general, is often fruitless in averting speedy death. In the most desperate cases the surface lesion is often insignificant, the infection following the lymphatic pathways, soon reaches the general circulation resulting in death from acute sepsis before any decided gross pathologic lesions have appeared at the seat of infection or in any of the internal organs. How rapidly general infections may take place has been shown by the experiments of Schimmelbusch, who found micro-organisms in the spleen five or ten minutes after infection of a wound. Colin and Niessen demonstrated by their experimental work that amputation a few minutes after inoculation of the ears and limbs of rabbits with pure cultures of anthrax did not protect the animals against generalization of the disease. Such cases in the human being fortunately are seldom met with, but when they do occur, the art of surgery is powerless in arresting the progress of the disease. Parenchymatous injections of solutions of carbolic acid or corrosive sublimate along the course of the inflamed lymphatics, and the internal use of alcohol in heroic doses promise the most, but in the great majority of cases the extension of the infection continues and terminates speedily in death from general sepsis. In the treatment of diffuse phlegmonous processes it is now customary to make free incisions, establish free drainage, and disinfect the cavity by flushing it freely with a safe and yet efficient antiseptic solution, such as a saturated solution of acetate of aluminum, a three per cent. solution of carbolic acid, or a 1–5000 solution of corrosive sublimate and apply to the part hot compresses wrung out of the same solution.

Closely allied to phlegmonous inflammations of the soft tissues is acute suppurative osteomyelitis, as it is caused by the same kinds of microbes, and results in more or less extensive destruction of tissue. The etiology and pathology of this disease are now well understood, and upon them is based the early operative treatment, which is generally indorsed by the profession at the present time. The early removal of the osteomyelitic product by operative interference, as a rule, relieves pain promptly, limits necrosis, guards against joint complications, and reduces the danger from general sepsis. Immobilization of the affected limb, in proper positions, and the exposure of the osteomyelitic focus by the use of the chisel or gouge as soon as a positive diagnosis can be made, are the modern resources, which have succeeded in greatly reducing the mortality of this disease, as well as its immediate complications and remote consequences.

Only a few years ago, the surgeons who paid special attention to diseases of the joints were enthusiastic advocates of early resection or arthrectomy in cases of tubercular joint affections. It was believed that such radical treatment would succeed in eliminating the local affection and in preventing the extension of it to distant organs by reinfection from the peripheral focus. Statistics prove that these hopes are unfounded, and conscientious surgeons have substituted largely in place of operative treatment, conservative measures. A change in practice has taken place, largely due to the beneficial effects obtained from intra-articular and parenchymatous injections of iodoform and glycerin. Resort to this treatment has been made in hundreds of cases, with the most satisfactory results. In about one-half or two-thirds of all cases of uncomplicated joint tuberculosis, this treatment proves curative. It is of special value in the treatment of tubercular abscess in communication with a tubercular joint or bone. From one to three or four injections usually suffice in obliterating the abscess cavity.

In considering the subject of malignant tumors, it must be acknowledged that the essential cause of carcinoma and sarcoma remains to be discovered. The science of surgery must first divulge the true nature of tumors before we can expect a decided advance in their more successful treatment. The essential features of the modern treatment of malignant tumors may be summed up very briefly as follows: Operate early and thoroughly. The treatment of inoperable sarcoma by injections of the sterilized toxins of the streptococcus of erysipelas and the bacillus prodigiosus has not fulfilled our reasonable expectations.

Operative interference is absolutely indicated in fractures of the cranial vault under the following circumstances: (1) All open fractures, including gunshot and punctured fractures. (2) Depressed fractures, attended by well-defined

symptoms, caused either by the depression or intracranial complications. (3) Rupture of the middle meningeal artery, with or without fracture of the skull. The indiscriminate use of the chisel and the trephine in the hands of the inexperienced practitioner is fraught with danger, and should not be encouraged by teachers and expert surgeons. Cerebral localization and aseptic surgery have made it possible to treat a few intracranial lesions successfully by direct operative interference.

The abdominal cavity was largely *terra incognita* to the surgeon of less than half a century ago. Today it is the favorite battle-ground of the average surgeon, and the select field of the so-called abdominal surgeon. Notwithstanding the wonderful improvements in the technic of operations upon the stomach, partial gastrectomy and pylorectomy have yielded anything but encouraging results. In nearly fifty per cent., the patients subjected to radical treatment for malignant disease of the stomach succumbed to the immediate effects of the operation. The speaker has opened the abdominal cavity for the surgical treatment of malignant disease of the stomach nineteen times, and only in one case did he find the disease limited to the organ first affected, and in this case the general health of the patient had been so much deteriorated by the obstructive pyloric carcinoma as to contraindicate a radical operation; in all of the remaining cases a pylorectomy or partial gastrectomy was out of the question, as the carcinoma of the pylorus or stomach had extended to adjacent organs, or had given rise to regional infections through the lymphatic glands sufficiently to contraindicate any attempts at radical removal of the disease.

The greatest onslaught of modern surgery has been upon the organs of generation, male and female. The future historians who will record the work of many gynecologists belonging to the present generation will have reason to express their surprise at what disasters the art of surgery has produced when plied in cases far in advance of a scientific foundation. Here and there we hear a feeble voice protesting against the indiscriminate surgery upon the organs of generation of the opposite sex, but the mutilating work continues in spite of such opposition and well-meant advice. When we arraign the gynecologists before such a representative body composed of representative medical men of this country for innumerable and inexcusable transgressions of the rules which ought to govern and control the art of surgery, we do not include the scientific, conscientious workers in that department of surgery, but our remarks apply to a class of routine operators which have recently grown to alarming dimensions not only in this, but in nearly every country which has been penetrated by the dim rays of so-called bold surgery. The new generation of doctors finds no longer satisfaction in practising their profession in some rural district. They have their eyes on large cities and have heard of enticing fees paid to specialists for insignificant operations. Why buy a horse and saddlebags when a fortune awaits them in devoting themselves to a specialty, more particularly gynecology? The recent graduate or the man who has become disgusted with country practice seeks a much employed gynecologist, follows his work for a month or two and returns to his prospective field of labor a full-fledged specialist. He is now ready to extirpate the uterus, remove ovaries and Fallopian tubes, sew imaginary lacerations of the cervix and perineum. Do you suppose that such an aspirant for gynecological fame ever examines a woman and finds her perfect? Is it not true that in nine out of ten cases he finds something to mend?

Laceration of the perineum is a favorite subject of the amateur gynecologist. The extent of laceration and the symptoms caused by it are not always carefully considered in deciding upon the propriety of an operation. The performance of an operation on the perineum in five or seven minutes still serves as an attraction for the lookers-on in many private hospitals and gynecological clinics.

The frequency with which women are being castrated is one of the most flagrant transgressions of the limits of the art of surgery. It is not unusual for one operator to exhibit five or six normal ovaries as the result of half a day's work. All kinds of excuses are made for this kind of surgery. Where is this wholesale unsexing of our female population going to end? The beginning of the end has come. The army of women minus their essential organs of generation is beginning to raise its voice against such mutilating work. The number of women who willingly sacrificed their ovaries to restore their shattered health without securing the expected relief has increased to an alarming extent. This sad experience has made the gynecologists more desperate and bold. It is difficult to say where this rage for the removal of the female sexual organs will end, or what organ will be the next battle-ground for the aggressive gynecologists. The clitoris, the vagina, the cervix uteri, the ovaries, the Fallopian tubes, the uterus and its ligaments, have success-

ively passed through a trying ordeal of operative furor. What the next fad will be is impossible to foretell.

The subject of genital surgery should not be dismissed without making a strong plea in favor of conservatism in the treatment of prostatic hypertrophy. Allusion is made to this subject because it is feared that when this operation on aged men for hypertrophy of the prostate becomes common property, and is indorsed by surgeons of high standing, it will be misapplied in the same way, probably to a lesser extent than the removal of normal ovaries. Men will be castrated for stone in the bladder, chronic cystitis and malignant disease of the bladder. It is not always easy or possible to make a positive differential diagnosis between simple hypertrophy of the prostate and some of the conditions which simulate it so closely. In doubtful cases it would be advisible to make the diagnosis sure by a suprapubic cystotomy before resorting to a mutilating operation, rather than remove the testicles and later discover an encysted stone or malignant disease of the bladder or prostate. Castration is such an easy operation that every tyro in surgery will be tempted to perform it upon willing subjects suffering from obscure affections of the bladder, complicating hypertrophy of the prostate gland. The Ramm-White operation deserves fair trial at the hands of competent surgeons, in well selected cases, but evil is apprehended in the future, not so much from the proper use as the abuse of this procedure.

ADDRESS ON STATE MEDICINE, BY GEORGE H. ROHE, M.D., OF BALTIMORE.

THE PURIFICATION OF WATER SUPPLIES

The most vitally important sanitary problem confronting American municipalities at the present day is, unquestionably, the supply of pure water for drinking and other domestic purposes. The widespread prevalence of typhoid fever may be practically looked upon as a result of the pollution of the drinking water. The importance, therefore, of having the latter of a pure quality is self-evident. In 1894 twenty-five of the principal cities of the United States had an average typhoid mortality of 39.6 per one hundred thousand of their population.

The numerous epidemics in this country and abroad, which have been studied with so much care by eminent sanitarians, have demonstrated the relation of infected drinking water to typhoid fever. While cases doubtless occur in which the disease cannot be traced to the water supply, these constitute the vanishing minority. In epidemics of cholera a similar relation exists between the outbreaks and extension of the disease to an infected water supply.

Pure water, or water free from all sorts of uncleanness is demanded to-day by the "sanitary conscience" of the public. We are therefore reduced to one of two alternatives, either to prevent the access of impurities to the sources of supply, or else to resort to some method of purification of the water itself. The City of New York has recently chosen the first alternative by purchasing large tracts of land bordering upon its source of water supply. By the removal of sources of pollution from the area of land so acquired the endeavor has been made to secure a pure drinking water. But the expense has been something enormous.

In Chicago, the extraordinary epidemic of typhoid fever from 1889 to 1893, led to the extension of the intake pipe in Lake Michigan to a distance of four miles from the shore. Since then, the typhoid mortality has been reduced from 159.7 per one hundred thousand in 1891, to to 31.4 per one hundred thousand in 1894.

In most instances, the changing of the source of water supply is quite impractical. Fortunately, there is at our hand, however, a means by which a source of supply once polluted or constantly polluted, can be rendered pure, namely, by filtration.

Formerly, filtration simply meant straining out from water all gross impurities, thus changing a dirty or muddy water into a clear and limpid fluid. It did not contemplate the changing of organic compounds into inorganic compounds, or the removal from the water of minute organisms, which we have learned to recognize as the causes of specific diseases. We now know that water may be perfectly clear and limpid, and yet be extremely impure. We also know that sewage water, full of organic matter and teeming with manifoid micro-organisms of various kinds can be rendered absolutely pure by filtration.

The experiments by the Massachusetts State Board of Health, conducted at Lawrence by Mr. Hiram F. Mills and Mr. Allen Hazen, proved conclusively that water, no matter how polluted, can be rendered absolutely safe and pure by simply filtering the same through sand-filters, provided certain conditions are observed regarding the construction of the filters, the rate of filtration, etc. Comparative studies of the efficiency of sand-filters and various processes of so-called

"mechanical filtration" confirm the opinion that sand filtration gives the best results in purification, at the lowest cost of construction and maintenance.

Koch discovered that the real filtration does not take place in the sand, but that by deposit from the polluted water a layer of mud is formed on the top of the sand, and that it is this layer of mud which retains the suspended constituents of the water. In the process of filtration, the important point is, first, that a proper layer of slime should be formed and that it should not be disturbed during the process of filtration, and that when, by further continuous deposit, it becomes too thick, and therefore, too impermeable to water, it should be removed. It has also been discovered that in the gradual wearing out of the sand layer it should never be allowed to get below a certain thickness—about 30 cm.—and that a certain speed, about 100 mm. per hour, must be maintained of the movement of the water through the mud layer. Daily or tri-weekly examinations of the water by a bacteriologist determine whether the filter is working properly or not.

London has used this system of sand filtration for her drinking water for upwards of forty years. The filter-beds of Berlin cover an area of thirty acres.

The cholera epidemic of Hamburg in 1892 furnished an object lesson of great value. Hamberg and Altona both draw their water supply from the river Elbe. In Hamburg the water was furnished direct to consumers without filtration; in Altona the water had been systematically filtered for a number of years. The Hamburg supply was drawn from the river at a point where there was comparatively little pollution, but the Altona supply came from the stream after it had received the sewage of the city of Hamburg, numbering eight hundred thousand inhabitants. Moreover cholera bacteria were even discovered in the Elbe water below the outlet of the Hamburg sewers.

In Hamburg about twenty-one thousand persons were attacked with cholera, of whom more than eleven thousand died during the epidemic. In Altona on the other hand there were five hundred cases, four hundred of which were shown to have been importations from Hamburg, thus leaving only one hundred cases traceable to infection in Altona. A remarkable improvement in the prevalence of typhoid fever attended the introduction of sand filtration at Lawrence, Mass.

In sand filtration, two processes must be kept in view; one, the straining out of the bacteria, and the other, the conversion of the organic matter into inorganic compounds. These imply, that the materials of which the filter is composed shall be sufficiently fine to hold back all suspended matter, and that a sufficient supply of oxygen shall always be present to oxidize it. In most natural waters, there is a sufficiently large quantity of free oxygen present to cause the oxidizing processes to go on continually, but in extreme cases of pollution, an extra supply of oxygen is necessary. This may be supplied by aeration of the water before filtration, or by conducting the filtration intermittently.

On the whole, it is probable that sand filtration must be regarded as the most efficient method of purifying a polluted water supply; and that, when carefully and intelligently managed, it can be depended on as a perfect safeguard against infection from that source.

THE PRESIDENT'S ADDRESS DELIVERED BEFORE THE ASSOCIATION OF AMERICAN PHYSICIANS, AT ITS ELEVENTH ANNUAL MEETING AT WASHINGTON, D. C., APRIL 30, 1896.

BY A. JACOBI, M.D.,
OF NEW YORK.

GENTLEMEN: The scrutiny of the program you have prepared for this meeting of the Association of American Physicians, yields an eloquent exposition of its scope and aims. The fellows who are offering their contributions to the discussions of these three days, have in the distant parts of the country, each by himself, and unknown to their far-away cooperators, acted the parts of different constituents of an organism. Indeed, whatever conduces to make up internal medicine, from the special biological study of a coccus to the prognosis in a particular disease, from the etiology of a morbid condition to its therapeutics, from the consideration of a local ailment to that of public hygiene, is well represented. Gathering up the apparently detached threads, I therefore find it far from difficult to express in a few words what I consider to be the relation of medicine, such as it is exhibited in this Association and on its program, to medicine as it is taught and practised, either undivided or in its specializations, and of this Association to its national sister societies.

At a time when a number of national special organizations had been in existence several years, it was founded, I take it, because the leaders felt that the natural tendency to the division of scien-

tific labor should be, not checked, but guided by a controlling hand, and that the independent position of internal medicine should be demonstrated and vouchsafed.

Since Boerhaave, aye, since Galen, specialties branched off from the original trunk of medicine. The accumulation of experience, the multiplicity of observers, the increasing depth of studies, the perfection of tools and instruments, and the limitation of the capacity of individual practitioners, at one time even the dictates of the Church have from century to century, and lastly, from decade to decade, added to the number of specialties in practice and of specializations in study. Indeed, at the present time, a medical man may do his full duty to his profession, be an expert largely quoted, the first among his peers, and a peer among the first, an authority of the first rank, without ever having paid the slightest public attention to the demands of social hygiene, or for years seen a single sick-bed. On the other hand, there are those most of whose time is spent and efforts exhausted in attending to the sick, both in hospitals and private dwellings. Their observations may be quite as correct as those of the microscopist and experimenter, but they are not so easily proven to be so. In their case it takes, as a rule, a large number of statistical data to establish facts as truths and worthy of acceptance, for, indeed, truth is not so simple as many a proverb will have it. The reason for this is manifest. The object of the microscopist is single, is one, and still mistakes are made; for explanations differ in regard to what has been seen, and corrections and refutations are numerous. That of the physician is complex, therefore more difficult. His subject is man, and usually man whose physiological functions are disturbed by a pathological process. His work is also more comprehensive, his aim higher than that of a practical specialist who claims to deal with a single organ. When we look upon modern specialties as they frequently are, not as they ought to be, practised, we have to admit that they suffer from the danger of limiting the view of the practitioner. An isolated organ is the center of his perpective, and everything not enclosed in his field of vision, which is occupied by the organ of his choice, is doomed to remain insignificant in his estimation. Moreover, the mercantile and mercenary spirit of the end of the century matures occasional eagerness for early reputation and social and financial success. The public is easily impressed by visible manipulations and manual dexterity, and unable to follow or correctly rate the results of unobtrusive and unornamental brainwork. Thus it is, that to establish himself in reputation and standing among laymen, it takes the accomplished physician as many decades as the young specialist years. On the domain of practical medicine, the specialties have gradually encroached. No cavity but has been invaded by the surgeon, no special organ ever so small but what has been appropriated by a specialist. Is it true, however, that medicine becomes more surgical or specialistic? Is it not rather to be demanded that surgery and the rest of the specialties should remain, or, more than hitherto, become medical?

It is not given to me to value scientific labor, beyond the personal happiness conveyed to the searcher for truth by the broadening of his mental horizon and by revelations never manifested before, except by the good it does to the race. *Nisi utile est quod faciamus stulta est gloria.*

The researches which have contributed most to the success of all branches of *surgical* medicine are the same that have added to our knowledge of a large number of infectious diseases and benefited both private and public hygiene. That is where the bacteriological hermit, the studious histologist, the bedside practitioner, and the public statesman join hands. That is where medicine proves itself to be the benefactor not only of the individual, but of mankind. Political economy and individual and public hygiene are equally interested in the progress of medicine. When society will have passed beyond the mire of mercenary wire-pulling and bickering, when every man will be a political being in the sense of Aristotle, with the tendencies of the statesman rather than those of the politician, when the welfare of the people and race will be the only aim of enlightened representatives, then the medical man will be either the legislator or his adviser, and medicine will take the place occupied in remote medieval times, before there were so many churches, by the Church. But to accomplish that end medicine must remain one and indivisible.

Looking over the programs of the Climatological, Pediatric, Gynecological, Neurological Associations, and the rest, you recognize subjects familiar to yourselves. Let them acknowledge their origin, and the ties are no longer severed. Surgical *science* is medicine. Its *art* only is what constitutes the specialist. The methods of surgical diagnosis are medical. The very sources of its practical success are the pharmacological, biological, and histological laboratories. The very best minds of both hemispheres were always

anxious to enforce the union of the *disjecta membra*. No science deserves its name unless enlivened by this idea. Imagine, for instance, anthropology to relinquish its throne and acknowledge the independence of its different branches. The collective studies of crania, or of hair, the peculiarities of the Esquimo tribe, the relationship of languages, they are branches of and contributions to science, not sciences. This knowledge of consanguineous unity was the cause of the formation of our triennial congress. From that point of view this Association, with its annual meetings drawing on, and combining as it does pathological anatomy, histology, bacteriology, chemistry, physics, and all the practical aids offered by the mechanic, the optician, and by all the specialties, whose number leaves nothing to be desired beyond that it might be smaller, and with its constant contact with the interest of the commonwealth, takes the place of the triennial congress. One of the wisest members, in my opinion, of this Association was once asked by me what he did in a certain case. His answer was: "Among other things, I prescribed a surgeon." One of the leading specialists of the country told me after he had inspected a volume of our transactions: "I know how to operate on an eye, and now and then I succeed in making a good brain diagnosis. After all, however, we do retail work. When I want statesmanship in the profession I look to internal medicine."

Among the constituents of scientific and practical medicine there is one which has not yet succeeded in conquering its legitimate place, viz., therapeutics. Fifty years ago in Vienna, and where its influence was paramount, the interest in man began at the autopsy. It had become, and occasionally still is customary, even with large minds, to scoff at the value of internal therapeutics. The effects of the knife, the actual cautery, the tourniquet, the local applications on the integuments are readily conceded. But the natural difficulties of directing and controlling the action of drugs on distant cell conglomerates, either fluid or solid, are often emphasized and exaggerated into alleged impossibilities. That is a mistake, for the merely empirical character of therapeutics, which, after all, has a value of its own, is to a large extent superannuated. The diagnostic methods of Laennec (with whose illustrious name that of Auenbrugger ought always to be thankfully remembered) and of Skoda, and the introduction of the thermometer by Wunderlich, enabled us to prove some of the local or general actions of medicines. The efficacy of local treatment was proven by Hebra in the treatment of scabies, in the very face of the nihilistic school of Vienna. Pravaz's invention, as ingenious as it was simple, facilitated local administrations with tangible and instantaneous effects. The separation of alkaloids, beginning with that of morphia in 1817, strychnia in 1818, caffein in 1819, added to the accuracy of effect and of observation. Experiments with drugs on animals have vastly contributed to the exactness of our medication, though it is true that every newly discovered fact is liable to be accepted or not with the protest that whatever happens *in corpore viti* need not be applicable to man. In that way we are mainly indebted to Wepfer who worked as early as 1679, to Magendie and his pupil, Claude Bernard, and to the greatest of them all, Karl Ludwig. Nor was it animals alone that were utilized to accomplish accuracy in the application of medicines. Observation of their action when they were given to the well and the sick has vastly increased our knowledge in spite of the absurd caricatures furnished by that erudite quack, Hahnemann.

Nor has chemistry and pharmacology, which was in due time separated from pharmacy, been idle. The changes undergone by medicinal agents were studied by Mitscherlich, Schmidt, Wormley, Horatio C. Wood, and Schmiedeberg, and the dependence of the effects of medicines upon their chemical structure by Richardson, Brown, and Frazer, with the final result of creating through synthesis new and powerful agents. One of the most promising observations was this, that certain bacteria are capable of immunizing animals against the action of certain poisons, either through the metabolic products of bacteria, or by the very serum alone of such immunized animals. Finally it was found that as the absence or the diseased condition of the thyroid gland caused serious disorders, so some of the latter could be corrected or cured by the administration in different ways of thyroid tissue or its extracts. These very facts, and the results of serum therapy, and the promises of organotherapy in general, which we expect to be fulfilled in the near future are most hopeful signs. We are, therefore, amply justified in believing that internal medicine will soon reap many of the fruits, thus far harvested by external medicine, from the fields of biological and bacteriological laboratory work.

This is more than hope. It is the more a certainty the more surely and frequently physiological and pathological functions are shown to be chemical. Bacteriology, advanced as it is beyond tentative beginnings and the overbearing claims of

youthfulness, does no longer pretend to cover the field of etiology. It recognizes the difference between the entity of a disease and its cause. All organic changes in the cells and protoplasm are either physical or chemical, or both. Bacteria cause local infection, usually primary, rarely metastatic in character, but never the constitutional symptoms of a disease. These are produced either by proteins or toxins, the products of the very microbic bodies, or ptomaines, the products of the cells in which the presence of microbes worked an abnormal metamorphosis. The latter, however, does not result from bacteric influence only. Chemical, mechanical, thermic changes, are apt to influence the normal vital processes, which again impress, or are impressed by, the peculiar individual disposition created by age, hereditary influence, previous illness, state of nutrition, nerve force, and the conditions of rest or exhaustion. What a wonderful and complicated chain of mutual influences and possibilities, and what subjects for study for this Association.

The normal vital processes depend on two powers, the cells and the blood.

The very structure and function of the former are acted upon or built up by the latter. Thus it appears as our master Virchow has lately pointed out, that finally we return to a species of humoral pathology, but not indeed to the crases and diatheses of old. For modern humoral pathology looks for the presence in the blood of actual agents mostly of chemical nature. Part of them has been shown to be so; in the case of others we have to rely on inferences. Still, with peptones, aceton, sugar, with acetic, lactic, oxalic, uric, and oxybutyric acids in the blood we are fairly acquainted; and the discovery of Fraenkel's thyreo-antitoxin proves to what extent the action of the organic juices is mainly, if not altogether chemical.

The interests of the practitioner and his patients, of medical science and the commonwealth, are equally served by these views when tested by practice. As an Association we have to deal with the interests of science and of the community; of the latter even more than it is willing to understand or to admit. We, however, need not be exhorted to continue our work. The misunderstood sympathy with the alleged sufferings of animals, and the agitations of the anti-vivisectionists —no matter whether merely misinformed or fanatical—must not swerve us from studying, from learning, and from serving mankind by combining our efforts for public purposes. The hygienic interests of the community are, or ought to be, in our keeping. Your Association being the scientific representative of internal medicine in America, ought to be recognized all over the Union as the scientific law-giver. What the New York Academy of Medicine is calculated to become for New York City, this Association ought to be able to be for the Union and beyond it through the scientific labors of its members. In order, however, to attain this destiny, let us not forget that medicine must be one and inseparable, now and forever.

Some of our colaborers have left us during the past year. Dr. James Edmond Reeves, who was a member since 1887, and died at Chattanooga, Tenn., on January 4th, at the age of sixty-six years, was one of those who happily blended a strictly scientific ambition, as exhibited by his "Practical Treatise on Enteric Fever," and his "Manual of Medical Microscopy for Students, Physicians, and Surgeons," also by his paper contained in Vol. V. of our Transactions, on "Some Points in the Natural History of Enteric or Typhoid Fever," with a sense of duty both as a public servant and a citizen. From his early professional years he interested himself, both as a fellow of scientific societies and as a health officer, in public hygiene. He was the author of the law creating the State Board of Health of West Virginia, and it was he who felt bound and was able to take up, single-handed, a successful fight against a "consumption cure." At a time when the practice of medicine is frequently degenerating into a trade, and the number of quacks, and especially consumption quacks, is swelled even from among the ranks of men armed with medical diplomas and possessed of official positions, his undoubted courage and moral strength are bright examples that should not be forgotten. What I said of the combination of special medical interests, and the instincts and aims of a good citizen, is also due to the memory of Dr. James West Roosevelt, who died in New York on April 11th. He was, though a member of this Association since 1889, one of the youngest of us, being but thirty-eight years old when he died. More extensive obituaries will refer to his various monographical contributions to medical literature. In Vol. VI. of our Transactions there is a paper of his on the "Frequency of the Localization of Phthisis Pulmonalis in the Upper Lobes." As he was versatile, enthusiastic, and unselfish, his participation in the fight against misrule in New York was active indeed. It will always be gratefully remembered. He was deeply interested in the efforts of the New York Academy of Medicine to abolish the pollution of the Croton water shed, and to secure national control of quarantine.

As death is busy causing losses, it is our responsibility to see that the ranks of the Association remain closed. There being, however, but few vacancies in our roll of one hundred, but few candidates will be presented to you for election. You recollect that in last year's meeting you declined to increase our membership, which is now limited to one hundred. The same proposition will be made again, to be voted upon next year. The class of men anxious to join, and capable of doing scientific work, is certainly growing. Now it is true that the Association has been justly conservative, but conservatism is not narrow. As it was the pride of every one of us to be one of the hundred, it will, when we conclude to facilitate new admissions, be our pride and happiness to know that no increase of membership will ever include all the Americans willing and able to render actual scientific services to universal medicine.

ORIGINAL ARTICLES.

SOME PRACTICAL REASONS FOR EARLY OPERATION IN APPENDICITIS.[1]

By R. HARVEY REED, M.D.,
OF COLUMBUS, O.,
PROFESSOR OF THE PRINCIPLES AND PRACTICE OF SURGERY AND CLINICAL SURGERY, IN THE OHIO MEDICAL UNIVERSITY, AND SURGEON TO THE PROTESTANT HOSPITAL.

In an an article on the surgical treatment of Chronic Catarrhal Appendicitis, read before the Ohio State Medical Society at its forty-sixth annual meeting, held at Sandusky in June, 1891, I referred to the practical uses of the vermiform appendix, and in closing, I drew the following conclusions, based on my limited experience at that time on the results of the surgical treatment of appendicitis: (1) That the appendix vermiformis is a useless rudiment. (2) That chronic catarrhal appendicitis is always dangerous, and liable to be followed at any time by hazardous and even fatal results. (3) That medical treatment is of little or no permanent value in this class of cases. (4) That the only safe and reliable method of treating chronic catarrhal appendicitis, and the only treatment that will promise permanent relief to your patient is prompt amputation of the appendix.

Since writing that paper, a great deal of literature has appeared, a great many theories have been advanced, and I am certain that the profession of to-day is much better versed in the diagnosis and treatment of diseases of the appendix than it was five years ago.

[1] Read before the Tri-State Medical Society, Chicago, Ill., April 8, 1896.

When it first began to dawn upon the profession that there was such a thing as appendicitis, and that peritonitis was usually a symptom rather than a disease, the differentiation between appendicitis and other diseases of the intestinal tract seemed to be the chief stumbling block. Medical men, more than now, objected to the knife and advocated the use of medicinal remedies, with hot applications combined with a large smattering of expectant treatment. It is true, not a few of their cases, then as now, got well, but while their expectant treatment was followed with success in a few cases, a large number terminated fatally, which doubtless could have been saved by an early operation. Very much to the discredit of the medical profession, appendicitis was taken up by the lay press, and became, to a certain extent, a fad. Medical men arrayed themselves against operations, while many of the surgeons favored them. These matters were discussed pro and con, until the average citizen was about as familiar with appendicitis as many members of the medical profession. Operators, however, disagreed in reference to operating; not a few advocated early operation; others advocated operating immediately regardless of the stage of the disease; others advocated waiting until pus formed, and still others advised never to operate in the first attack. With all this division of opinion among operators, saying nothing of those who did not pretend to operate, with the numerous deaths which followed, whether cases were operated on or not, is it any wonder that the laity became alarmed and confused.

I shall not enter into the discussion of the anatomy or pathology, or even the diagnosis of appendicitis, but shall proceed at once to the consideration of some practical reasons for early operation:

1. In discussing this subject I wish the gentlemen of this Association to bear in mind that the appendix vermiformis is a useless appendage that is simply a rudiment in man of what is a valuable portion of the intestinal tract in some of the lower animals.

2. I wish to put myself on record that even a healthy appendix is a dangerous portion of the intestinal tract, and liable at any time to make trouble for its possessor.

3. I wish you also to bear in mind that the simple removal of a healthy appendix is not a dangerous operation, and is not followed by unfavorable results, if properly performed.

In my experience it is delay that has increased my mortality record in these operations. In those

cases where consent was obtained for an early operation, I have been enabled, by the removal of the appendix, to save many lives; but when, for any reason, delay has occurred until perforation, suppuration, and septic infection have taken place, I have either lost the patient, or he has been obliged to lie for weeks and suffer from a multitude of complications, not the result of the operation, but plainly the result of delay. In this connection I wish to offer as evidence of the importance of an early operation the following case:

Samuel Wilson, age forty-one, weight 225; a merchant, resident of Columbus, O., was taken ill with pain in the right iliac region, July 1, 1894, at which time he called his family physician, Dr. J. U. Barnhill, who found him exceedingly tender over McBurney's point, with temperature 100°. His diagnosis was "suspected appendicitis." July 2d, his temperature had risen to 101°, and there was severe localized pain in the right inguinal region, with constipation. The next day his temperature was 101°; local tenderness more marked. Diagnosis of appendicitis was made, and he was advised to go to the hospital for operation. On the 4th his temperature remained 101°, pulse 98; pain intense, and distinct tenderness over the region of the appendix. On the 5th of July his temperature was found to be 102°, pulse 110, and pain less severe. At this time I was called in consultation, confirmed the diagnosis, and advised operation as soon as possible. On the 7th there was slight delirium; temperature 102½°, pulse 120. On the 8th his temperature suddenly rose from 102° in the morning to 104° in the afternoon; tenderness more marked, with decided evidence of an abscess. He was admitted to the Protestant Hospital and prepared for an operation the next day, July 9th.

Assisted by Drs. Barnhill and Means, I operated, opening a large abscess in the right inguinal region, which involved the appendix, as well as the head of the cecum. Not less than a quart of pus was evacuated. The parts were thoroughly flushed with 1–3000 bichlorid. We found that the appendix had sloughed off, and that circumscribed necrosis had taken place in the walls of the cecum about three inches above its head, causing an opening at least an inch in diameter, which allowed the fecal matter to discharge into the abscess cavity. This was all thoroughly washed out with peroxid of hydrogen, followed with bichlorid. The opening in the bowel was closed with a Lembert suture and the abscess cavity packed with iodoform gauze. The cavity was thoroughly cleansed from three to four times a day, but on the 11th of July, the second day after the operation, a fecal opening was discovered. The abscess cavity closed rapidly by granulation, leaving a fecal fistula.

On August 7th we made our first attempt to close this opening, through which the mucous membrane of the colon freely protruded. After having thoroughly cleansed it with antiseptics, we proceeded to denude the mucous membrane for at least an inch and a half in width, extending this process completely around the fistulous opening. The denuded surfaces were then carefully sutured to each other and the integument closed with silk sutures. This operation, however, proved to be a failure, and in a few days the sutures sloughed out and the patient was left in the same uncomfortable and undesirable condition.

A second attempt was made at closing this fistula on August 24th, at which time we made an incision completely around the fistulous opening, carrying our dissection just to the verge of cutting the peritoneum. We then inverted that portion of the bowel which protruded through the abdominal walls, bringing the surface of the outer coat of the intestine together, in the closing of which we used four rows of sutures. The wound was then washed out antiseptically and the integument closed with silkworm-gut. This held for several days, but eventually gave way, and another fistulous opening was the result. Various other operations, with a view of closing it, were resorted to, but all failed to accomplish the desired end.

Unfortunately, the patient, in spite of all we could do for him, continued to vomit from a week to ten days after each operation, thus putting extra tension on the sutures. This, I believe, to a large extent caused infection, and the re-establishment of the fistula. To avoid this we made two trials with cocain anesthesia, with better results, so far as emesis was concerned, and hence better results from the operation. After these operations the wound gradually closed up and the patient's general health was improved, and December 21, 1894, he was discharged from the hospital apparently well.

Soon after his discharge a slight amount of fecal matter made its appearance along the line of the fistulous track, which was now largely composed of cicatricial tissue. This, however, did not annoy the patient a great deal, and after having gone through such a serious ordeal as I have briefly described, he was willing to put up with some inconvenience, provided it did not increase. September 7, 1895, he became decidedly worse; a complete artificial anus formed, and for over a month he did not have a natural stool, the fecal matter all discharging from the opening in the bowel which was so large that my hand could readily be passed into the ascending colon, and the ileo-cecal valve distinctly felt below, together with the curve at the commencement of the transverse colon above. Water injected by a fountain syringe into the rectum would freely escape through the artificial anus without any pain or disturbance to the patient.

Mr. Wilson was again admitted to the Protestant Hospital September 15, 1895, at which time the protrusion of the bowel was about the size of

my two fists. After carefully studying his case, I decided that all the failures heretofore were due to fecal infection together with continued vomiting after the operation, and I then proceeded to devise a plan with a view of overcoming this obstacle. I finally decided to perform an ileo-cholostomy with the Senn bone plates, making the artificial opening into the ascending colon just below the curvature of the transverse colon, with a view of changing the course of the fecal current, and switching off the lower portion of the ileum together with the cecum up to the point at which the ileum was joined to the ascending colon.

This operation was performed October 17, 1895. Before operating the colon was cleansed as thoroughly as possible, the head of the cecum was packed with pellets of absorbent cotton, and the artificial anus covered completely with antiseptic gauze, so as to exclude, as far as possible, infection. The usual abdominal opening was made just below the curvature between the ascending and transverse colon. An opening about an inch and a half long was then made lengthwise of the colon, which admitted one of the Senn bone plates. Having fastened the plate to its proper place, the opening was carefully guarded with a sponge by an assistant, so as to prevent any fecal infection. I next brought up the cecal end of the ileum, and made an opening in that at a point to correspond with the opening already made in the colon, introduced the bone plate, and completed the operation *secundum artem*, including a running suture along the plates so as to doubly secure them.

The patient got along nicely after this operation without any difficulty worth mentioning. It was very interesting to pass the finger into the colon and watch the process of absorption take place in the bone plates, which on the sixth day came away, a mere film about the thickness of a piece of tissue paper.

The final operation for the closure of the artificial anus was made December 16, 1895. The patient was carefully prepared for this operation by a restricted diet for four or five days previous, during which time we allowed him to drink all the water he could possibly indulge in, for a dual purpose. First, to relieve the hunger due to the restricted diet and, second, to obviate thirst after the operation and prevent vomiting. The morning of the operation, the colon was cleansed by a thorough douching, and every arrangement made for an aseptic operation. Before commencing the operation, I was interested to know the size of the opening where the artificial union of the two intestines had been made, and consequently passed my hand up to the opening and found that I could pass both the index and middle fingers, without any effort on my part, or pain on the part of the patient. This convinced me that the opening between the two intestines was sufficiently large. I first packed the colon with small pellets of cotton, for the purpose of preventing fecal infection and to act as a guide after I had entered the abdominal cavity. I then brought the integumentary edge of the artificial anus, together with a continuous suture of catgut, in order to prevent any possible escape of fecal matter during the operation proper. Assisted by Drs. Means and Cole, I then proceeded to enter the abdominal cavity by making an incision parallel to the rectus muscle, the entire length of the artificial anus, along its inner margin. Having entered the peritoneal cavity, it was very easy to distinguish the ascending colon from the ileum on account of it having been filled with cotton. I could readily pass my finger down to the lower end of the ileum and locate the ileo-cecal valve below, while it was easy to locate the artificial attachment of the ileum to the colon above. Having positively determined my anatomical bearings, I then dissected completely around the artificial anus until I had freed it from its lumbar attachment, when I commenced to invert the entire mass, first with a row of kangaroo-tendon suture, between the catgut suture, above-mentioned, and the bowel, and continued until four rows of these sutures were inserted, and the bowel so completely inverted that there was a depression in the wound instead of a protrusion. You will observe we had made (including the continued suture) five rows of sutures, four of which were made of kangaroo-tendon. The wound was then thoroughly washed with sterilized water and closed with heavy silk suture, covered with iodoform gauze and sealed with iodoform collodion. From this time on the recovery of the patient was without interest. In a few days after the operation, the cotton with which we had packed the head of the cecum, passed per rectum, and shortly after that, natural stools were established. When discharged from the hospital, January 24, 1896, he was having two natural stools a day without any trouble. At this time he is in good health and weighs 218 pounds.

During the past winter I was called early in the morning to a case in which an acute attack of appendicitis had set in, the night before, in a young man about twenty years of age. My advice was an immediate operation; but for various reasons it was delayed. At four o'clock, the same afternoon, there was evidence of perforation of the appendix, with profound shock, followed by septic peritonitis, and for a time it seemed as though he would die from collapse. Having rallied sufficiently, he was admitted to the Protestant Hospital, but operative interference was still delayed until it was evident that nothing but an operation could possibly save his life. I operated under a protest in my own mind and found the abdominal cavity filled with pus, with numerous points of necrosis extending along the intestinal tract and a general septic condition, so marked that it was evident that death would ensue in a few hours, which it did.

Another case was admitted a few days later, in which there had been a question of diagnosis, and

from the incipiency of the attack until the operation, several days had elapsed. As soon as the diagnosis was satisfactory an operation was made, but septic infection had done its work. Numerous pockets of pus had formed, necrosis of a portion of the intestine had taken place, and again the patient was relieved from his suffering by the hand of death.

Gentlemen, these are serious matters for the surgeon, and when I come before you advocating early operation for appendicitis, I do it because I believe it is the only safe and reliable plan of treatment. I believe it offers, to the patient first and to the reputation of the surgeon second, more than any other line of treatment that has yet been tried. Why wait for a second attack? Why wait to see whether perforation will take place and pus form? It is true, perforation may not take place and pus may not form, or, if it does form, it may rupture into the head of the cecum and escape, and your patient get well; but is that an argument in favor of non-interference, when so many of our patients who wait for something to turn up will die! It is true that many of these cases will have recurrent attacks, some as high as half a dozen or more, and still live through each of them, but is that any argument why we should allow a patient to remain in a condition which endangers repeated attacks of sickness, any one of which may snatch him from time to eternity without a moment's warning?

Allow me to offer as testimony in favor of an early operation the case of a young gentleman who was just about to graduate in medicine, and who, at seven o'clock in the evening, was taken with pain in the right iliac region. Before nine o'clock next morning appendicitis was diagnosed. An immediate operation was made by my colleague, Dr. Baldwin, assisted by Dr. Means and myself. An inflamed appendix was found, just ready to burst and covered with wandering leucocytes, which only needed the presence of pus microbes to convert them into poisonous pus. The appendix contained several enteroliths, which were doubtless the cause of the inflammation, and which at any moment might have caused pressure necrosis, followed by perforation and septic infection. But what was the result? This young man got well without a bad symptom, and is now at his home enjoying life, in contradistinction to another professional gentleman, who, a few days later, in the city of Columbus, was taken with this treacherous disease, was operated by an eminent surgeon of our city three days later, and died of septic peritonitis on the seventh day following the attack.

Gentlemen, these are only a few of the many cases which we cannot ignore. We, as professional gentlemen, must respect the experience we earn in the field of practice. We must set aside theory and be governed by facts, and when we are called to the bedside of a case of appendicitis, ask ourselves the question, what course shall we pursue that will afford this patient the greatest protection?

Allow me to give just a few quotations from the the experience of others in the treatment of appendicitis. In an able article by Dr. Meyer of New York, on "When Shall we Operate for Appendicitis?"[1] he says:

"It is a great misfortune, I believe, for those who were stricken by appendicitis within late years that the 'early operation,' originally advised by Dr. McBurney, had to give place, by virtue of medical evolution, to the so-called 'timely operation.'

"Generally speaking, no doubt it is more scientific in the treatment of patients to individualize: thus also in appendicitis, it is more scientific not to find the indication for the removal of the appendix given as soon as the diagnosis of its inflammation has been made. And I for my part am convinced that the medical profession will continue to carefully weigh the pros and cons with reference to operation in each case of appendicitis. Yet at the same time I am firmly convinced that if we could give one hundred equally serious or equally light cases of appendicitis to two equally trained surgeons, the one who believes in and always does an early operation will save a greater percentage of lives than the other, who only takes the knife in hand during the attack when he considers it to be time."

In an exhaustive article, entitled, "Should the Appendix be Removed in Every Case of Appendicular Abcess?" by J. Wm. White, M.D. of Philadelphia,[2] he says:

"I believe, for exampie, that few, if any, would dissent from the following rules: Immediate operation is indicated whenever the onset of a case of appendicitis is marked by both suddenness and severity; whenever, during even a mild attack, the symptoms at the end of forty-eight hours are unrelieved or are growing worse; whenever in cases seen later a firm, slow-forming, well-defined mass is to be felt in the right iliac fossa: whenever at any time a sudden increase in the acutenesss of the pain and a rapid diffusion of tenderness occur; whenever there is good reason for believing the appendix infection to be tubercular in character; whenever attacks of any type have been numerous, or are increasing in either number or gravity, or have unfitted the patient for work or activity, or have caused local symptoms which are permanent and persistent, or have at any time put the patient's life in great danger."

I might continue to multiply the evidence in favor of early operation, but I do not deem it necessary, for I doubt whether there is a surgeon within the hearing of my voice who cannot corroborate, by cases that have come under his own observation, the statements I have made to-day. I have lived through the era when a case of perforated appendicitis was diagnosed peritonitis

[1] *Medical Record*, February 29, 1896.
[2] *University Medical Magazine*, March, 1896.

with a grave prognosis. I have watched the surgeon give relief to these cases by the use of the knife. I have seen the pendulum swing to a point where it was advised to operate on all cases; I have seen it return to the opposite extremity, in which some of the best surgeons have advocated delay, and during all this time I have had personal experience in each of the different methods advocated, but, after having tried them all I have returned to my former faith, and unless better evidence shall be furnished in the future than in the past I shall continue to advocate early operation in appendicitis.

CHANCRE OF THE TONSIL AND TONGUE, WITH REPORT OF FOUR CASES.

By T. C. EVANS, M.D.,
OF LOUISVILLE, KY.;
LECTURER ON OPHTHALMOLOGY AND LARYNGOLOGY IN THE KENTUCKY SCHOOL OF MEDICINE, ETC., ETC.

BEFORE reporting the following cases I wish to say a few words in regard to the diagnosis of primary syphilis of the mouth and tonsils. Some recent experiences lead me to believe that the profession generally greatly overestimates its difficulty, and that many are inclined to take the throat surgeons' diagnosis of chancre of this region with a liberal allowance of salt, and to consider such diagnosis a little better than a bold guess. While chancres of this region differ in some respects from the cutaneous or muco-cutaneous genital chancre and lack some of its characteristics—still, they present to the careful observer an appearance, and clinical history sufficiently distinctive to warrant the diagnosis of primary syphilis, or at least a stay of proceedings until the appearance of additional evidence in the shape of secondary manifestations.

Taking into consideration the fact that all ulcerative lesions of the mucous membrane of the mouth and pharynx are almost certainly malignant, tubercular, or syphilitic, we find a diagnosis can be arrived at by exclusion. As far as the tonsil itself is concerned we may go still farther and say that an ulceration beginning in the tonsil means either carcinoma or syphilis. Carcinoma will be excluded by the fact that the pain, the enlargement of the tonsil and the glandular involvement, all precede the ulcerative process by two or three months. Then again the ulceration of carcinoma is, in itself, characteristic in that the ulcerated area is elevated and its edges overhang the surrounding mucous membrane, and is surrounded by a bright red areola.

The greatest difficulty in the diagnosis of chancre of this region lies in its differentiation from the ulcerations of the secondary and tertiary stages of syphilis. Chancres of the tonsil present the ordinary characteristics of primary lesions in general except that they involve a larger surface, and that the induration, as a rule, is not so well marked. The ulcers are sluggish and covered with a grayish-white exudate. They are of varying depths and have sloping edges. The involvement of the cervical and submaxillary glands is marked, constant, and characteristic. This unilateral grandular enlargement I consider the most important and distinctive point in the differential diagnosis.

The superficial ulcerations of secondary syphilis are excluded by the fact that they are always bilateral and more or less symmetrical—the glandular involvement is slight and, of course, also bilateral.

The tertiary lesions may be single or multiple. The ulcer is crater-like, deeply excavated with shelving edges; the glands are but little, if at all enlarged, and are not sensitive to pressure. By a little tact and skill in questioning and examining the patient, enough evidence can usually be obtained to either exclude or establish the history of infection by the genital route.

Some months ago I made the following report to the Louisville Clinical Society.[1]

CASE I.—On February 14th, Dr. A. said he had experienced some pain on swallowing, and had a slight elevation of temperature for the past three weeks. On examination I found the left tonsil considerably enlarged. A little anterior to the center of the tonsil was a deep, oval-shaped ulcer, about three-quarters of an inch in length, the long diameter being from above downward; the anterior margin of the ulcer involved that part of the tonsil covered by the anterior pillar of the fauces. The free margin of this anterior pillar was also involved in the ulcerative process. This ulcerated margin was from one-half to three-quarters of an inch in length; the ulcer, both on the tonsil and the anterior pillar of the fauces, was covered by a grayish-white membrane or exudate. The entire soft palate and uvula were very much congested, but not edematous. The deep, cervical glands were much enlarged, producing quite a perceptible external deformity.

The patient was a robust man of thirty-two years. I was satisfied that the ulceration was syphilitic, and from the general appearance of the throat, the clean-cut appearance of the anterior pillar, the ulceration of the tonsil, the absence of edema of the palate and uvula, the marked enlargement of the cervical glands, I felt almost sure the lesion was primary. I requested him to remove his clothing, when I found that over his

[1] *Journal Cutaneous and Genito-urinary Diseases*, October, 1895.

chest and back his body was the seat of a papular eruption—the typical and unmistakable papular syphilide. The diagnosis was a complete surprise to the patient, who, by the way, is a married man. He could think of no possible exposure, and said that, so far as he knew, he had not a single syphilitic among his clientele, which is composed almost wholly of a rural population. I think his statement is correct as far as he knew, as he is an honorable gentleman.

On my advice, he sought the opinion of a number of throat specialists, as well as the genito-urinary surgeons. At his next visit he told me they had all concurred in my diagnosis, and he accordingly began with antisyphilitic treatment.

I wish to supplement this report by adding two cases of chancre of the tonsil and one of the tongue.

Case II.—On September 4th, J. H., aged twenty-five, came into my clinic at the Kentucky School of Medicine, stating that he had a sore mouth. On examination, I found three or four abrasions of the lips and mouth that looked like the superficial ulceration of the second stage of syphilis. The young man denied having any sore about his genital, and a careful examination showed the truth of his assertion. Making a careful examination of the throat, I found a deep, circular ulcer of right tonsil. The ulcer was situated at the extreme upper part of the tonsil, and almost hidden by the anterior pillar of the palate, and was covered with a grayish-white deposit. The induration could be easily made out by palpation. The cervical glands were greatly enlarged on the right side, and exceedingly painful. He said the glands had been enlarged for three or four weeks. The man was living with a prostitute, who was under treatment at the same clinic for mucous patches of throat and mouth. The diagnosis of chancre of the tonsil was made at the first examination. The patient left the clinic and passed into the hands of a physician in private practice, from whom I learn that he developed a typical secondary eruption, leaving no doubt as to the diagnosis.

Case III.—On December 10, 1895, I saw in consultation, Mrs. S., aged sixty-three. She had an ulcer on the right tonsil of six weeks' duration. The ulcer was about the size of a dime, slightly excavated, rather irregular in its outline, and covered with a grayish deposit. She complained of pain on deglutition and pain in the right ear. The tonsil was pushed well out toward the median line, and was considerably larger than we would expect in a person of this age; the hypertrophy was more apparent than real, from the fact that it was forced out of its bed and pushed into the fauces by the enlarged cervical glands. The swelling of these glands was sufficient to produce quite a perceptible external deformity, and was painful and sensitive. The diagnosis of chancre of the tonsil was made, and the patient put upon palliatives and placebos to await developments. The ulceration afterward extended to the anterior pillar of the palate and was exceedingly obstinate and tedious; its healing was not complete until the end of the fourth week. Two weeks after the healing of the ulcer of the tonsil, and twelve weeks from the time of its inception, the belated secondary manifestation made its appearance in the palms of the hands, then on the neck and face, and later she developed the typical secondary lesions of the mouth and throat.

Case IV.—A lawyer, aged thirty years, was referred to me by a dermatologist for an opinion in regard to a throat affection. On examination, I found the apex of each tonsil covered by a pseudo-membranous mucous patch, the lesions being symmetrical. He said three months prior to the time he came to consult me he noticed a small ulcer on the end of his tongue on the dorsal surface of the tip a little to the left of median line. It was rather painful, but the principal inconvenience was from a feeling of soreness or stiffness of the muscles at the root of the tongue and left side of the neck. As the ulcer persisted for five or six weeks, he became uneasy, lest the trouble might be specific or malignant, and went to a neighboring city for medical advice. He was seen by three different physicians, all of whom assured him it was not specific, but was probably due to some hepatic or alimentary disorder. They prescribed Carlsbad water for the correction of his supposed disorder, and he returned to his home. At the time of my examination, the ulcer of the tongue had completely healed, and its site was marked by a smooth glistening spot, entirely devoid of papillæ. With the exception of some suspicious-looking spots on the palmar surface of the hands, the lesion of the tonsil was the only manifestation of secondary syphilis. But these were sufficiently characteristic to warrant the diagnosis of syphilis. A few days later, several syphilides made their appearance on the face and neck. He also developed mucous patches around the anus

Chancres of the tongue are less common than of the tonsils, as shown by the following statistics:

Bulkley, in his recent work, "Syphilis in the Innocent," in discussing the location of the primary lesion, says that extra-genital chancres "form possibly ten per cent. of the whole."

The same author has tabulated the location of 9058 recorded cases of extra-genital chancres; of these there occurred on the lips, 1810; on the breast and nipple, 1148; buccal cavity, 734; fingers and hand, 462; eyelids and conjunctiva, 372; tonsils, 307; throat, 264; tongue, 157; chin, 146; cheek, 145; trunk, 100; nose, 95; arms, 87; peri-genital, 77; legs and thigh, 73; forearm, 59; neck, 47; gums, 42; forehead and temples, 37; ears, 27; vaccination, 1863; cupping and pleb-

otomy, 745; circumcision, 179; tattooing, 82. It will be seen from this table that three and a half per cent. of all extra-genital chancres occur on the tonsil.

Then we must take into consideration the probability that a large proportion of the 734 recorded as occurring in the buccal cavity, and the 264 in the throat were, in fact, chancres of the tonsil.

I think it probable that next to the lips the tonsil is the most frequent seat of extra-genital chancre, and that possibly ten per cent. of all extra-genital chancres are tonsillar. The mucous membrane of the palate and faucial pillars, presenting as it does a smooth, dense tissue, covered with squamous epithelium, offers little chance of infection. Hence it is not unreasonable to suppose that the syphilitic virus passes over this part of the alimentary tract, and finds in the open crypts of the tonsils a field most admirably fitted for its protection and growth. In most instances the infection takes place in a tonsil already hypertrophied, which seems to afford a favorable condition for the development of the disease. The early development of the secondary eruption appears to be rather characteristic of the tonsillar chancre. This is probably due to the large size of the initial sore and to the fact that the tonsil is so intimately connected with the lymphatic system, the eruption making its appearance in from two to four weeks. In my last case the eruption was delayed until the twelfth week. The eruption is, in most cases, papular in character, still further confirming the rapid absorption, as the appearance of the papular syphilide is usually delayed until the the third or fourth month.

The earlier writers on diseases of the throat dismiss the subject of the method of infection with the bare statement that "chancres of the tonsil are due to bestial practices"—a statement that later investigation has shown to be incorrect and unjust. While it is unfortunately true that a small proportion are undoubtedly contracted in this way, by far the larger proportion are traceable to other causes, and most of them have been innocently acquired. Among the many causes alleged in the cases reported may be mentioned kissing, pipes, cigars, glass-blowers instruments, musical instruments, drinking vessels, forks, spoons, feeding bottles, of which transmission by kissing seems to be the most frequent. In only one of my four cases was it possible to trace the source of infection. In looking up the question of extra-genital chancre I have been more than ever impressed with the great injustice done the profession, as well as the public, by the common custom of teachers and text-books considering syphilis as exclusively and essentially a venereal disease, forgetting or ignoring the fact that it is a contagious disease due to the entrance of a specific virus into the system; that it is venereal only in the sense that illicit sexual relations afford the most favorable conditions as well as the most frequent opportunity for its propagation. This undue attention to the venereal aspect of the disease, or, more properly speaking, the want of attention to its non-venereal aspect, has done untold harm by causing many an unfortunate but entirely innocent patient to feel himself degraded and disgraced, knowing as he does that the occurrence of syphilis is almost invariably associated with some loathsome sexual disorders, both by the the laity and the medical profession, To add to his humiliation, he knows that his statements in regard to the trouble to his family, intimate friends, and even his physician, are at best taken with a large degree of allowance. The failure on the part of the physician to appreciate the fact that syphilis may be transmitted by many other means than by improper sexual relations causes many cases to go unrecognized, as in the one reported, which had been seen by two physicians prior to the time the patient came to this city, neither of whom seem to have suspected the cause of the trouble. A similar lesion on the genitals, with the enlarged glands in the groin instead of neck, would doubtless have been diagnosticated by either of them without hesitation.

CLINICAL LECTURE.

OSTEO-SARCOMA OF SCAPULA, FRACTURED CLAVICLE, DOUBLE HARE-LIP.[1]

By ROSWELL PARK, A.M., M.D;
OF BUFFALO, N. Y.,
PROFESSOR OF SURGERY, UNIVERSITY OF BUFFALO.

Case I.—This first patient is one on whom you saw me operate ten days ago, removing the left scapula on account of an osteo-sarcoma. You can see plainly the T-shaped scar of operation, which has, however, healed by first intention without suppuration. I will pick out the silkworm-gut sutures that were inserted to hold the deeper tissues in apposition; the superficial catgut sutures are already absorbed, except a few ends that project from the skin and that may be dislodged without trouble. Nothing further in the way of a formal dressing will be required. The patient can already move the arm quite freely, though extension of the humerus is not yet possible. With further restoration of the muscles, and with practice, he will gain a better control over the extremity

[1] Delivered at Buffalo Hospital.

so that the loss of the shoulder blade will not cripple him so much as might be expected.

Case II.—This boy has a broken clavicle, which was set at the Fitch Hospital a week ago. He came here several days later. The result is a good one, there being a very little overlapping of the fragments. There is a projecting subcutaneous spicule of bone that has alarmed the patient somewhat, but we have reassured him that it will be absorbed in the process of repair. I am particularly glad to have the opportunity to show you this case at the present time, as it was only yesterday that I described the proper treatment of such fractures to the senior class, in the didactic course. The indication in fractures of the clavicle is to pull the shoulder upward, outward and backward. If the backward pull is sufficient, the curved surface of the thoracic wall will inevitably direct the shoulder outward. I have described to you a mild method of treatment, which, nevertheless, suffices for some cases, and which consists in keeping the patient flat on the back, with a pillow between the shoulders, so that the weight of the arm and shoulder tends to overcome any over-riding of the fragments of the bone. The present case has been dressed with the posterior figure-of-eight bandage. Measuring with my eye, the distance from the spine to each acromion, I can distinguish no difference on the two sides, hence the overlapping must be slight indeed.

I want to show you to-day the Moore dressing, which takes advantage of the peculiar decussation of the fibers of the pectoralis major, those arising highest on the clavicle passing to the lowest point on the humerus, and *vice versa*. The principal deformity that we have to anticipate in fractures of the clavicle is the pulling upward of the inner fragment by the contraction of the sterno-cleido-mastoid. Now, by pulling backward and outward on the humerus, the pectoralis major is put on the stretch and the action of the sterno-cleido-mastoid is opposed and the deformity prevented. It is not enough, when there is a tendency to upward displacement, to put the humerus comfortably at the side of the chest. A decided backward and outward pull is necessary to counteract the muscular action from above, and if we also raise the outer fragment of the clavicle by raising the shoulder and holding it in this elevated position, all the indications are met. Dr. Moore's double figure-of-eight dressing can be extemporized from a sheet, or shawl, or even a blanket, so that it is practically always at hand, however far away you may be from ordinary medical and surgical supplies. The bandage should be about six or eight inches broad, or a little narrower for a young person, and at least two yards long. I first apply the middle of the bandage under the elbow, then take a turn with each half around the humerus, the posterior part in front, the anterior part behind it, while, if necessary, an assistant holds the arm in the position of upward, outward, and backward strain which I have described. Even so much of the dressing exerts a beneficial action in diminishing deformity. You will notice that I carefully avoid passing the bandage over the site of fracture, as the pressure between the cloth and the jagged ends of bone might, very easily cause ulceration. In order to hold the shoulder in position, a second turn is necessary about the neck or opposite shoulder. If I pass the bandage around the neck, I not only fail to draw the shoulder backward, but the patient is rendered uncomfortable by the choking. Hence the bandage should be passed behind the neck and around the opposite shoulder, as originally pointed out by Dr. Moore. Simply to add to the patient's comfort, a pad of cotton should be placed in the opposite axilla. As a matter of illustration I have rather overdone the stretching of the bandage, and I will relax it a little before fastening it in the back. Still, it must be remembered that any dressing will stretch a little so that it should be put on a little tighter than you mean to leave it finally. Flannel is not a suitable material for such a dressing as it is so elastic that it always yields after it has been on a few hours. Again, it is better to use old cotton cloth, or at least that which has been washed and ironed, than the unbleached cotton as it comes from the factory. Few persons realize how much new cotton will yield. The tricksters on the stage, who allow themselves to be bound with strips of cloth, appreciate the difference and manage to extricate themselves from bonds that seem absolutely secure, simply by using new cloth that will stretch. Following the turns of the bandage you will see that it is not strictly a double figure of eight, but three half-loops of the figure, a figure-of-eight and a half. The dressing needs to be supplemented by a sling for the hand and forearm, and perhaps, by passing a broad roller bandage around the trunk, so as to hold the arm in position of absolute quiet. This second roller does not include the arm, but passes through the loop between the elbow and the ascending spica turn. I hear somebody thinking if he is not actually asking whether this is a comfortable dressing? I cannot say that it is; but in fact I know of no fracture dressing that is thoroughly comfortable. I will reapply the dressing on the opposite arm, so that those of you on the other side of the amphitheater may see exactly how it is done.

In some cases of fractured clavicle, where there is little or no tendency to displacement, it is enough simply to hold the arm quiet. We may make, for example, a triangular sling supporting the forearm, hand, and elbow, with the ends tied behind the shoulders. This dressing, which is a modification of the Mayor scarf, will suffice in a small proportion of cases. In my own work, I use either the Moore dressing or Sayre's adhesive strips which fulfill the same indications. Simply on account of the inconvenience of removing the plaster, I will illustrate the adhesive strip dressing by applying pieces of roller bandage. The strips are about three inches wide and a yard long. The first one is passed around the upper end of the humerus, and is then pulled backward and toward the opposite side of the body, and is pressed against the back and side, where it adheres. The forearm is now flexed and a strip is run along the forearm, turning upward at the elbow, following the line of the humerus, and then crossing the back to the sound shoulder, and thence again down the hand and forearm, the two ends overlapping. This dressing, like the Moore's, or any other, may be applied so as to be utterly worthless, or it may be made

snug so as to hold the parts in the proper position. When the second strip is applied the shoulder must be elevated as far as possible.

While we are waiting for the next patient to be anesthetized, I wish to show you the dressing for fracture of the jaw. A broad bandage, about four inches wide and two feet long, is slit up the middle from each end nearly to the center, so as to make a chin support with four tails. To make a solid support for the chin, a piece of sole leather may be soaked and rendered pliable, then fitted accurately to the normal contour of the chin. But I prefer to take a little canton flannel or lint, sop it in a cream of plaster-of-Paris, and mold a splint which will set in a few moments to any shape desired. This is padded and bound to the chin by the four-tailed bandage, whose lower tails are brought up and tied over the vertex, while the upper ones are brought around the neck below the occiput. While this is the essential dressing I like to reenforce it and provide against its slipping, by applying a starch bandage over all.

CASE III.—I have shown you this winter several cases of hare-lip, including one or two in which there was not only a complete defect of the lip, but a failure of development of bone. To-day I show you a baby in which the intermaxillary bone, meeting with no opposition to its growth, has developed extensively, throwing forward the middle portion of the lip, which the Germans call the philtrum, and producing the appearance of a snout. Six or seven children of the same parents have shown no deformity. The child is brought in, not only with complete permission for the use of surgical measures, but with the plain expression of the desire—though not so crudely worded—that the baby be sent home either cured of this terrible disfigurement or in a box. This probosis must be forced backward to the level with the other parts of the lip, and then the defect on each side of the intermaxillary portion must be closed. The child is only four months old and is unable to withstand any protracted operation or severe hemorrhage. I shall, therefore, perform the operation in two sittings, contenting myself to-day with restoring the philtrum to its normal level. The first general indication for operation is plainly to remove a V-shaped piece of the septum and allow this restoration to take place, thus reducing the anterior deformity. I must be careful, however, not to sacrifice the intermaxillary portion of the alveolar arch, since it contains the rudiments of at least two incisor teeth, and their loss would be a serious matter. Neither do I wish to sacrifice the philtrum, or the middle of the lip, to which the lateral portions of the lip are to be hereafter fitted. I shall, therefore, remove part of the septum, well back from the lip, and the intermaxillary projection. On account of the vascularity of the parts, it is necessary to sponge freely and to quickly check the bleeding from the divided septum. Now, after taking out this V-shaped piece of bone, I can press the proboscis back where I want it. The nose will be somewhat flat, but in relieving such deformities as these, it is no part of the contract to fit a person for a "beauty show." I will apply the Pacquelin cautery, both to check hemorrhage and to guard against infection, for the mouth cannot be kept thoroughly aseptic and the charred surface will be less liable to absorb toxic matters than the fresh bleeding wound. After the child leaves the table, one of the nurses will hold a sponge firmly against the roof of the mouth, at the site of the operation, for half an hour or more, so as to prevent any oozing. Three or four times a day, the nose and mouth will be sprayed with a hydrogen peroxid solution. After ten days or two weeks it is probable that we can get union of all three parts of the lip by the usual method of suture.

MEDICAL PROGRESS.

Active and Passive Immunity to Cholera, Typhoid Fever, and Allied Diseases.—As a result of investigations covering a period of a year and a half, conducted in conjunction with Durham of London, GRUBER of Vienna (*Münchener medicinische Wochenschrift*, 1896, No. 9, p. 206) has found that a high degree of long-continuing immunity may be conferred upon guinea-pigs by the intraperitoneal injection of cultures of cholera bacilli, of typhoid bacilli, and of the bacilli coli communes rendered innocuous by chloroform, or by being heated to 140°. The immunity thus conferred relates to infection and not intoxication. The destruction of the bacteria in actively immunized animals, as well as in those protected by means of the serum of immune animals, is attributable to the activity of the bodily fluids, the polynuclear phagocytes playing only a secondary rôle. The blood and fluids of immune animals contain anti-bodies, which act within the bodies of actively and passively immune persons in the same way as they act outside. In passively immune persons no reactive transformation of the anti-bodies takes place. These anti-bodies have nothing directly to do with the destruction of the bacteria, which takes place as a result of the action of the alexins always present in the bodily fluids. The essential action of the anti-bodies consists in causing the bodies of the bacteria to undergo swelling, as manifested by stickiness. For this reason the anti-bodies may be designated glabrificins. As a result of the swelling of the bacteria the alexins can gain entrance to their bodies, and thus cause their destruction. In this process the glabrificins are used up, so that the effect depends upon the amount of immunizing fluid used. Active and passive immunity are essentially alike, depending upon the presence of glabrificins in the bodily fluids. Glabrificins have been found in animals thirteen months after the last immunization. Each bacterium has its own specific glabrificin, although the action of this is not absolutely but only relatively specific. The glabrificins are certainly derivatives of the body of the bacteria, but are only produced by transformation in the body of an immunized animal, probably through the action of the macrophages.

Successful Ligature of a Non-Traumatic Aneurism of the Vertebral Artery.—HUFSCHMID (*Archiv für klinische Chirurgie*, 1896, B. lii, H. 1, p. 23) has reported the case of a man, fifty-eight years old, without a history of syphilis, who, while at stool, with the head resting in the hands and the elbows upon the thighs, suffered rather vio-

lent flexion of the head upon the neck by the slipping of the left elbow. He at once felt a lancinating pain in the left side of the neck, and at the end of a week noticed in the same situation a swelling about the size of a hazelnut, quite free from pain. Without inflammatory manifestations the swelling increased to the size of a hen's egg in the course of four weeks. There existed, beside, general arterio-sclerosis. From the time of the accident there had been difficulty in swallowing, and at first also frequent nausea. The tumor, which was included between the junction of the lower and middle thirds of the left sterno-cleido-mastoid muscle—by which it was covered—and the angle of the jaw, was distinctly pulsatile and compressible. Its surface was smooth and pressure induced nausea. Over the tumor crossed a vessel of the size of the carotid, compression of which obliterated the temporal pulse. Compression of the common carotid lower down controlled the pulsation in the larger vessel overlying the tumor, but not that of the latter itself. In the further progress of the case it was observed that the left pupil was smaller than the right, and that the former did not react to light and in accommodation as well as the latter; but no noteworthy differences in the ophthalmoscopic conditions of the two eyes could be made out. The knee-jerks were enfeebled, but there were no other signs of locomotor ataxia. A diagnosis of aneurism of the vertebral artery was made, and operative relief undertaken. An incision, not quite three inches long, was made from the level of the larynx, at first along the posterior margin of the sterno-mastoid muscle and thence at a distance of a finger's breadth, to the supraclavicular fossa. To freely expose the lower pole of the aneurism and the beginning of the vertebral artery the clavicular portion of the sterno-mastoid was divided a little more than an inch above the clavicle. A ligature was applied on either side of the aneurism, the divided sterno-mastoid united with catgut, and the wound, except at its lower angle,—where a strip of iodoform gauze protruded,—closed with silver and silk. After the lapse of more than a year the tumor was replaced by a small, hard mass, free from pulsation, which occasioned no trouble. The left pupil was smaller than the right. Soon afterward the patient died suddenly in an apoplectic attack, but no autopsy could be secured.

Sterilization of Catgut.—KOFÉND (*Wiener klinische Wochenschrift*, 1896, No. 11, p. 188) details the method of sterilizing catgut employed in Gussenbauer's Clinic at Vienna. The crude strands are scrubbed with the aid of green soap and placed, for the removal of the fat, in ether, which is renewed until the fluid remains clear. They are then washed in absolute alcohol until all air-bubbles and all water have disappeared. Next the rolls, placed between layers of gauze, are exposed for two or three hours in a hot-air sterilizer at a temperature between 130° and 140° C. They are now immersed for a day or two in a one-tenth per cent. aqueous solution of mercuric chlorid, and finally preserved in a 1–1000 solution of mercuric chlorid containing 50 parts of glycerin.

Sudden Death from Occlusion of the Coronary Arteries.—OESTREICH (*Deutsche medicinische Wochenschrift*, 1896, No. 10, p. 148) has reported the case of a military officer, thirty-two years old, who, without previous illness, was seized on arising from bed on the day following his wedding with unconsciousness, speedily followed by intense cyanosis and death. There was no history of rheumatism, syphilis, alcoholic excess, chronic nicotin poisoning, or other possible cause of heart disease. Upon *post-mortem* examination the myocardium was friable and presented fragmentation of its muscular fibers. Just above the right aortic valve was a thrombus, about the size of a cherry-pit, attached by a delicate pedicle to the wall of the aorta, and which was so situated as to cover the orifice of the right coronary artery. This vessel was partially filled with liquid blood; its walls were thin and delicate, in places marked by yellowish spots, but free from calcareous deposits. The left coronary artery also was occluded by a thrombus about one-third of an inch long; beyond, it contained a small amount of liquid blood; its walls were thin and presented isolated yellowish spots.

THERAPEUTIC NOTES.

In the Treatment of Hemoptysis, SCARPA (*Semaine Médicale*, 1896, No. 12) recommends the administration thrice daily of from twenty to fifty drops of a combination of equal parts of fluid extract and tincture of hydrastis canadensis. One may begin with the smaller dose and, should it fail to control the bleeding, increase by ten drops at a time to the larger. The determined dose is continued for several days after the cessation of the hemorrhage. When the hemorrhage is associated with, and aggravated by obstinate cough, from gr. ⅓ to gr. ½ of codein, or from gr. ⅙ to gr. ⅓ of morphin hydrochlorate, may be added to each dose. It is always essential that both preparations be perfectly fresh.

The Treatment of Multiple Papillomata of the Larynx.—As the result of an extended experience, NAVRATIL (*Berliner klinische Wochenschrift*, 1896, No. 10, p. 202) pursues the following plan in the treatment of multiple papillomata of the larynx: In all instances, intra-laryngeal removal is to be practised if possible. In children, when symptoms of laryngeal stenosis becomes urgent, prompt tracheotomy is performed, followed by intra-laryngeal curetting of the affected areas; in case of recurrence, the curetting is repeated, but through the opening in the trachea, until there is no further return. In the case of adults, if intra-laryngeal measures have proved unsuccessful, laryngo-fissure is practised, and all of the new formation carefully removed.

For Epilepsy.—

Take of

Antipyrin,	1 dram.
Ammonium bromid	3½ drams.
Strontium bromid,	1 dram.
Solution of potassium arsenite,	40 minims.
Extract of solanum carolinense	10½ drams.
Water, to make	6 fl. ounces.

Mix.

Dose: A dessertspoonful or more twice daily.

—*Gaz. hebd. de Méd. et de Chir.*, 1896, No. 19.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to The Medical News will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 Fifth Avenue (corner of 18th St.), New York.

SATURDAY, MAY 9, 1896.

THE ASSOCIATION OF AMERICAN PHYSICIANS—OUR PROFESSIONAL "IMMORTALS."

There are few more interesting and industrious bodies meeting in this "association month" than that which has just adjourned at Washington. It was composed solely of those who have proved their devotion to scientific medicine, gathered from every part of the land, and presided over by one of the most impressive and inspiring figures in American medicine. The proceedings were marked by a dignified simplicity, an intellectual directness and vigor, and an utter absence of parliamentary or personal tactics of any sort, such as conspired to make the beholder proud of his profession. The session was a most intructive one to the profession at large, not so much from the intrinsic interest and importance of the subjects discussed, for the program was at first sight a distinctly disappointing one, but from the facts developed during their consideration and the point of view from which they were almost unconsciously approached.

In the first place the general drift of its work distinctly indicated that the study of the bacteria alone, as the sole or even chief factor in disease, has reached its high-water mark, if indeed the tide has not already begun to ebb. Although nearly half the program was occupied by papers upon bacteriologic studies, in only two of these was the germ itself made the chief point of interest, and its discovery—and naming—a sufficient excuse for the communications. In all the other papers the central and controlling ideas distinctly and overwhelmingly related to the resistance of the tissues to attack, the effect of soil upon virulence, the possibility of modification of even specific forms by environment, as was especially illustrated in the most valuable papers of Drs. Flexner, Bolton, and Theobald Smith, reported in another column.

The advance in medicine, which we owe to this enthusiastic study of the bacteria for their own sake, is of simply incalculable extent and value, and the resultant discoveries will always remain a monument and a model of thoroughness, conscientiousness, and devotion in research, forming one of our highest claims to the proud title of "scientific" medicine. Doubtless the great bulk of the profession will hail with cordial satisfaction the prospect that the brilliant and tireless powers of our laboratory-workers are beginning to be turned toward the physiological aspects and factors of the great problem of disease. To speak figuratively, the bacteriologic foot of bacterio-pathology has made a long stride forward, and the time has come for its physiologic fellow-foot to follow.

Much still remains to be done from the purely bacterial standpoint; in spite of the magnificent feats already suggested by the names, Metchnikoff, Hankin, and Cattani, we cannot but feel that we are barely upon the threshold of the great problems of immunity, of susceptility, of resistance. It is not improbable that we shall find that the fixed and floating cells of our bodies are to the fiercest bacilli as a Greek phalanx to a horde of Parthians, and that our tissues normally secrete antitoxins, which are as deadly to hostile bacteria as the proteid of the rattlesnake and the morphin of the poppy are to the enemies of their species.

GENITO-URINARY DISEASES. — RECENT ADVANCE IN THE KNOWLEDGE OF BACTERIURIA.

Within the past ten years, so much has been added to our knowledge of the etiological relation of micro-organisms to various conditions of the urine, to inflammations of the genito-urinary tract, and as causative factors in urinary infection or poisoning, that it may be said that a new epoch has been inaugurated. A vast number of contributions have appeared, many of which are valuable, many only suggestive, others being simply cumulative evidence, while some possess only an ephemeral interest. Such, however, is the importance of this accumulated mass of knowledge that its critical analysis and succinct portrayal will be of benefit to the physician, as well as to the gynecologist and surgeon.

There is a very prevalent opinion that the urine of individuals not suffering from any disease or presenting any symptoms is always free from microbic admixture when in the bladder. It is now well known that this fluid may, in passing through the urethra, carry with it some or many of the microbes which are the constant, and usually harmless, denizens of that canal. Recent observations, however, show very clearly that the urine, when still in the bladder, may contain many micro-organisms, some of which, under (to them) favorable circumstances, may become pathogenic, and produce more or less severe illness. The published cases of bacteriuria, as it is termed, are as yet not numerous, and their teaching will not admit of succinct didactic description, nor warrant any systematic deductions or generalizations, but they are very suggestive, and open up a line of investigation which, with further critical study, will throw much light on many ephemeral and severe morbid states, the origin of which now, very frequently, escapes recognition, even by intelligent and painstaking physicians. The most important article on this subject is that of Krogius (*Sur la Bacteriurie, Annales des Organ. Gén.-Urin.*, March, 1894), which is based on the study of eight cases, in which the urine was examined microscopically, and from specimens aseptically obtained cultures were made. A study of these cases, of which three were men and five were women, shows that the ages of the patients varied between twenty-eight and sixty-four years, and that in the men there had been antecedent urethral trouble, which had been presumably cured, and had not been followed by any functional or organic affection of the urethra or bladder. In the histories of the females, it was found that some had had antecedent pelvic affections, and had been operated upon; others had borne children, while others still had been catheterized. In some of these cases, without known exciting cause, and without any bladder symptoms, the urine, which always was acid, became fetid, more or less opaque, and loaded with bacteria. In one case only there was moderately increased frequency of micturition. A noticeable feature in some of the cases was a condition of ill-health, of which the chief symptoms were attacks of chills and fever and emaciation. In the case of one man, the health was in no way impaired. It is significant that in the urine of all of these cases the bacterium coli commune was found in large quantities by culture, and that local treatment by nitrate of silver instillations caused the micro-organism to disappear, and that then the general condition of the patient either improved or became normal.

The cases of Krogius are important by reason of the careful bacteriological studies which were expended on them, while the observations and cases of Roberts, Ross, Doyen, Enriquez, Schottelius, Reinhold, and Stenbeck, who have written on this subject, do not carry with them much scientific weight, being useful and, in a measure, suggestive as preliminary communications concerning an, as yet, little understood pathological condition. Krogius remarks of his cases that they are not ordinary instances of urinary infection, and that they present entirely different features from those observed in cystitis. There is one point concerning these cases not brought out by Krogius, which has struck me forcibly, and that is that in some of them there had been antecedent lesions of the urethra, which seemed to have gotten well. Now, in these cases the urine in the bladder later on contained the bacterium coli commune, and the following questions suggest themselves: Did these micro-organisms lurk in the then presumably healthy urethra or bladder after the cessation of the inflammation?

or, was a morbid focus left, in which they remained in a latent and inoffensive state? In some cases the suspicion is warranted that the microbes were carried into the bladder in the act of catheterization. As to the local symptomatology of bacteriuria, most of the cases thus far observed show that there is no evidence of bladder trouble, and the opacity of the urine and its bad odor were in several the only disquieting features. In two cases, there was evidence of mild vesiclar irritation. Severe systemic reaction was only observed in a few cases, and was entirely absent in the majority, and it promptly ceased when local medication was instituted. It is remarkable to observe how, in some cases, the bacterium coli commune was found in the urine in enormous quantities, and yet there was no disarrangement of the health, while in a few there was evidence of what we may suppose was more or less severe urinary poisoning. It is impossible in these cases to say why cystitis was not produced by the virulent microbe so constantly found. This immunity was probably due to the integrity of the bladder tissues. It is to be noted that in five cases bacteriuria became more pronounced when the urine became mildly albuminous, and the question suggests itself, was the fluid then more favorable to microbic growth than it had been before? The occurrence of systemic symptoms during the existence of bacteriuria is at present difficult of explanation, and the question presents itself, can these microbes or their toxines pass through mucous membranes in appearance healthy? This is still another question for the future to decide.

In two cases (Krogius and Stenbeck), at the autopsy the bladder tissues to the eye seemed normal. It will require microscopical study to establish the anatomo-pathological conditions of bacteriuria.

Bacterial urine has a cloudy, even an opaque, appearance, and if it is shaken up, an undulatory or eddying motion may be seen, as if it contained some impalpable powder. Its odor is described as stale, and it may be so penetrating that it pervades the whole room.

The cases thus far considered may be classed under the provisional title of essential bacteriuria. In addition, it is well to remember that in the course of all acute, and perhaps chronic, infectious diseases, there may be a secondary bacteriuria. Then, again, we may recall to mind the fact that Ultzmann, who was one of the first to write on this subject, states that he has found bacteria in the urine of persons who live in marshy, malarial, and unhealthy regions, in those living in a bad atmosphere, and who stay for long hours in dissecting rooms and morgues. Perhaps in these cases the microbes are eliminated through the kidneys, and, as a result, the system is spared. The foregoing considerations show very clearly that we are not yet even on the threshold of the knowledge of bacteriuria, and that much and many-sided study and observation and many years will be required before the subject can be said to stand upon a scientific basis.

Robert W. Taylor, M.D.

ECHOES AND NEWS.

The Medical Department of the British Army intends to send a complete apparatus for skiagraphy with the Nile expedition. This is to be especially adapted to field use and easy transportation.

Owing to a high-handed usurpation of power by the Government of South Australia, in the management of the Adelaide General Hospital, the entire medical staff has been caused to resign. In so doing they receive the undivided sympathy of the profession, both in Australia and in England, and the Colonial Government will find it difficult to import respectable medical men to fill the vacancies thus created, a course which has been threatened.

At the last meeting of the New York County Medical Association, the Committee on the Relations of Physicians and Hospitals, Dr. George T. Harrison, chairman, made an extended report, of which the following is an extract:

"We have held many sessions, have listened to much testimony, and have found many witnesses, all agreeing that a plan of making nominations of attendants in the public hospitals has been adopted. This plan bars out the profession at large, and delivers all clinical material over to the control of the colleges, ostensibly for the benefit of the students, but really tending to the construction of a monopoly, which prevents any opportunity for the development and higher education of that large and able body of consultants who are not identified with the teaching faculties, thus making consultation fees professional perquisites. . . . Finally, from evidence submitted, it does seem to us as if there had been a successful attempt to construct a 'charmed circle,' entrance to which should be granted to very few, and then only by personal pull with the faculties, quite irrespective of scientific attainments. In other words, our matured opinion is that the so-called 'reorganization' was merely a conspiracy

to control the whole medical patronage of New York and County."

The report was adopted by the association.

Professor T. R. Fraser, of the University of Edinburgh, reported his scientific investigation of serpent venom to the Royal Institution of Great Britain, in a lecture on March 20th. He has been able, by gradually increasing administrations of the poison, to immunize rabbits until they could receive, without injurious effects, fifty times the minimum fatal dose, and during five or six months they safely received enough of the venom to kill 370 animals of the same size and species. In his experiments Professor Fraser chiefly used venom obtained from the cobra of India, although that from several African, Australian, and American reptiles was also employed with similar results. The blood serum of the immune animals was found to be antidotal when used, and to this serum the name "Antivenene" has been given. Another curious observation was that when the antivenene, or even the cobra venom itself was introduced into the stomach, a sufficient amount of the antidotal substance either found its way into or developed within in the blood currents to protect the animal against one and a half times the lethal dose injected subcutaneously.

Dr. James P. Parker of St. Louis, editor and proprietor of the *Annals of Ophthalmology and Otology*, died recently at forty-two years of age.

The official annual report of the State Commission in Lunacy for New York shows that on October 1, 1895, there were 20,216 inmates of insane asylums within the State. Of these more than 9000 were in the institutions of New York and Kings counties. The increase of patients in all the asylums had amounted to 1131, during the year then completed.

It is reported by cable to the lay press that Dr. Playfair has withdrawn the appeal from the recent decision of the now famous suit, and that efforts are being made for a final settlement. He has offered Mrs. Kitson $45,000, which she refused; but consented to accept $42,500 and the settlement by Dr. Playfair of all costs, the latter amounting to about $10,000.

On the 14th of April the French Academy of Medicine awarded the St. Paul prize of $5000, jointly to Messrs. Roux and Behring for their discovery of the diphtheria antitoxin.

A woman, residing near Mayfield, Ky., recently gave birth to five children at one accouchement. Four of the infants weighed four and a quarter each, and the other five pounds. All are in good condition and give fair promise of living.

One of the metropolitan papers has been devoting attention to the microscopic examination of the street dirt found adhering to the dress-skirt of a lady after an afternoon's shopping in New York. It reports to have obtained from one skirt, besides innumerable innocuous and unclassified organisms, the germs of fever, influenza, anthrax, and diphtheria. This means of transferring virulent matter from the streets to the house is, without doubt, a frequent one, and very naturally suggests two very important sanitary reforms, to-wit: cleaner thoroughfares and shorter skirts. The sense of supreme security which the new woman feels in this particular must be regarded as some compensation for her more or less complete self-denial of the ordinary female garments.

Columbus Hospital, a new charitable institution, located on East Twentieth street, New York City, was opened last week. It was formerly a part of the Post-Graduate School and Hospital, and is conducted by the Sisters of the Sacred Heart. Its capacity is limited to one hundred beds. Upon the rôle of its medical staff are some of the most talented physicians and surgeons of New York.

A cycling club for doctors is being organized in Brooklyn, N. Y. The movement originated among the students at the Long Island Hospital Medical College, but has now included a large number of the busy practitioners.

A novel tour for fashionable American physicians is proposed. Its promoters limit the party to one hundred, who will be selected from graduates of American universities, irrespective of particular schools of practice. These are placed under the direction of Dr. Gowing Middleton of Paris, and will visit in turn all the principal watering places and spas of Europe, thus acquainting themselves with the comparative value for the benefit of their future patients. The party is expected to leave New York City early in July and return in September.

By private letters from Central America, a most frightful epidemic of measles and mumps is reported to be raging in Costa Rica. More than ten thousand children are estimated to have died from these maladies during a period of three weeks. All official reports are vigorously suppressed, for commercial reasons.

The following not improbable story has found its way into the columns of the lay press: "Alfred Tennyson was once greatly humiliated by an eminent Scotch surgeon and professor in the Edinburgh University, who was entirely devoted to and wrapped up in his profession. Tennyson had occasion to go to him at one time to consult him in regard to some affection of the lungs. Years afterward, he returned on the same errand. On being announced, he was annoyed to find that the professor had no recollection of his name or face. He mentioned the fact of his former visit, but still the professor seemed not to know who he was. But when the professor had put his ear to the poet's chest and listened to the sound that the old ailment had made chronic, he at once exclaimed: 'Ah, I know you now! I remember you by your lung!' And Tennyson was the poet-laureate."

Sir William Priestley, Professor of Obstetrics at Kings College, and grandnephew of Dr. Joseph Priestley, the discoverer of oxygen, is the Unionist candidate for

Parliament from the Universities of Edinburgh and St. Andrew's.

ARRANGEMENTS have been made for two new courses in the second year at the College of Physicians and Surgeons of New York. One is in bacteriology, by Dr. T. M. Cheesman, and the other is in nervous histology, by Dr. Van Giesen.

THE *Virginia Medical Monthly*, so ably conducted by Dr. Landon B. Edwards for almost a quarter of a century, has been changed in name and frequency of publication to a semi-monthly.

THE June number of the *Buffalo Medical Journal* will be exclusively the product of medical women. Every detail will be placed in their hands, and it is needless to say that their best efforts will be in evidence when the next issue of this reliable periodical greets its readers.

DR. SUTER of Herkimer, N. Y., has proven by experiment that the heat developed by bullets during their passage is not sufficient to render them aseptic, as is generally stated. He found, at least, that the bacillus of anthrax would survive the ordeal, and infers that it is not safe to consider bullets sterile of the other germs.

RECENT investigations quoted in the current number of *Science* establish the fact that the essential poison of *rhus toxicodendron* can be nothing but an oil. Hence water will not remove the poison from the surface, but alcohol will, if applied freely.

A SERIAL known as the *Archives of Clinical Skiagraphy* is soon to appear in London, edited by Dr. Sidney Rowland. The first plate will be the osseous system of a child. Others will follow, showing obscure injuries of the bones entering into the formation of the knee-joint. The first issue will contain six plates.

THE Royal College of Surgeons, England, has awarded the Jackson prize to Dr. A. A. Kanthack for an essay upon tetanus, and the Walker prize to Dr. H. J. Stiles, for the best work on cancer.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Forty-seventh Annual Meeting, held in Atlanta, Ga., May 5, 6, 7, and 8, 1896.

(By Telegraph to THE MEDICAL NEWS.)

GENERAL SESSION.

FIRST DAY, MAY 5TH.

The meeting was called to order at 10.30 o'clock A.M., by the president, R. BEVERLY COLE, M.D., of California.

Prayer was offered by the REV. DR. MCDONALD, after which addresses of welcome were delivered by DR. FRANK M. RIDLEY and HON. JOHN TEMPLE GRAVES.

Announcements were then made by the chairman of the committee of arrangements, after which PRESIDENT COLE delivered his address. (See page 505.)

SECTION ON SURGERY.

FIRST DAY—MAY 5TH.

The Chairman, DR. C. A. WHEATON of St. Paul, in making the annual address, reviewed at some length the history of this section of the association, and mentioned the names of many men who have been prominent in its work in years gone by. He deplored the fact that many of these men too often absent themselves from these meetings, as it deprived the section of their counsel and assistance, which is so absolutely essential to its success. Among other leaders in surgery years ago, he mentioned Sir William Jenner, Morton, Wells, and Duncan. He stated that he hoped all present would add to the laurels of the American profession, and amalgamate and strengthen this organization. In his opinion, there was not a successful specialist in any branch to-day who was not, in a large measure, dependent upon general medicine for his following and success, and therefore he was obligated to attend these gatherings, to participate in its labors, and reap its justly-earned benefits. In conclusion, Dr. Wheaton said: "If a man is of stout heart, a good campaigner, and has a large income, he may be able to attend all the other association meetings, but to this one he should pledge a special fealty, because of its national character, its cosmopolitan personality, which makes it so interdependent, and, finally, because the character of work done by this section reflects, in a large degree, the quality of the whole."

DR. CARL BECK read a paper on

SUBPHRENIC ABSCESS IN ITS RELATION TO PYOTHORAX.

He stated that of five cases of subphrenic abscess, which he had observed, only twice was he able to make a correct diagnosis before operation. The fact that subphrenic abscess is very often confounded with pyothorax is well known, and such errors impress one gravely with the necessity of widening his limited diagnostic knowledge upon the subject. In referring to the treatment the author stated: "The history is the most important guide in differentiation. In subphrenic abscess there is generally a history of a previous abdominal disturbance. There is no history of cough and expectoration as in pyothorax. The heart is little, if at all, displaced, and there is no ectasy of the thorax or of the intercostal spaces. In the lungs vesicular breathing is found below the clavicle, the pectoral fremitus is also clearly perceptible. There is a well marked limit to the region of vesicular breathing below which the expiration murmur is replaced by amphoric sounds. Deep inspiration pushes the boundary line of the vesicular breathing much further down into areas in which formerly no respiratory murmur could be perceived. This would indicate a well-marked separation between the lungs and the abscess cavity, the boundary line of the lungs protruding toward the abscess cavity during deep inspiration. It is sometimes impossible to distinguish an encysted pyothorax from a subphrenic abscess. The pathognomonic signs of such effusions urged by Leyden were absence of cough and expectoration, slight displacement of the heart

and rapid change of note if the patient is rapidly turned. According to my observations, however, pleuritic effusion, particularly pyothorax, sometimes occurs without these symptoms." Dr. Beck discussed at some length the method of treating subphrenic abscess, and stated that the same aseptic precautions should be observed in this as in any other operation.

"If," said the author, "the first trial of the exploratory needle result negatively, the needle should be reintroduced several times into different portions, as the cavity may either be of small extent, may contain a cheesy accumulation, or may be divided into several minor cavities by adhesions. In the first event a cavity may be missed altogether by the exploratory needle, and in the second, the needle being introduced into the solid cheesy mass, it can draw no pus. After each negative result, a wire should be pushed through the needle, which must not be of too small a caliber. Thus some pus, which had remained adherent to the inner surface of the needle, will become attached to the wire. Occasionally it will be useful to fill the syringe with sterile water after the operation and force the water through the needle into a clean dish. In case cheesy masses are present, small particles are sometimes drawn into the caliber of the needle which cannot be seen with the naked eye, but which by being mixed with the sterile water, can be recognized under the microscope. In case the microscope does not give sufficient information, resort should be had to cultures of the fluid. T. Brown, in a case of subphrenic abscess, which he took for pyothorax until after operation, found cultures of the bacillus coli communis in the aspirated pus. He very properly emphasizes that, when pus from this region yields on culture, a mixed or pure growth of baccillus coli communis, there is a strong probability that the point of suppuration is situated below the diaphragm. The treatment of subphrenic abscess is practically the same as that of the pyothorax, that is, resection of a piece of rib. Only resection secures a sufficiently wide opening for thorough evacuation."

Dr. Alexander Hugh Ferguson of Chicago, read a paper upon

THORASCOPLASTY IN AMERICA (SCHEDE'S) AND VISCERAL PLEURECTOMY, WITH REPORT OF CASES.

Thorascoplasty as first done by Schede is an heroic measure for the otherwise hopeless cases of chronic empyema, and consists of the removal of the chest wall. Dr. Ferguson described his method of operating, and stated that some cases are not cured in spite of any operation performed for their relief. In his opinion, the fact that amyloid degeneration and tuberculosis does not contraindicate this operation, as stated by Schede, is only true within certain limits. The author first performed Schede's operation in July, 1895, in which case a good result was obtained. Healing by first intention was secured, and the patient was able to be out in a very short time. In spite of careful treatment for five months after the operation, owing to the fact that a long central sinus had not closed, the operation of visceral pleurectomy was performed, which resulted in the patient's complete restoration to health. This operation has been performed by several men in America since it was first instituted in this country in October, 1893, by Dr. George R. Fowler of Brooklyn.

Dr. Ferguson's paper was well illustrated by excellent photographs and drawings.

Dr. Bayard Holmes of Chicago, in discussing Dr. Ferguson's paper, said he had performed three operations of a similar nature, and two of the patients were now alive and well. There was no improvement in the third case, and the patient subsequently died of tuberculosis. The only adult on whom the speaker had operated, was a man, thirty-five years of age, who had been suffering with empyema which had been neglected for more than a year. In this case two attempts had been made to close the cavity by the Estlander operation before the operation described by Dr. Ferguson was performed. After the third operation the patient made a good recovery, although, it was necessary later to do two or three operations for the removal of infected bone, where the ribs had been infected from a discharge of pus.

Dr. James H. Dunn of Minneapolis, said he had been much interested in the past few years in the operation referred to by Dr. Ferguson, but that in his opinion most of the cases that have been operated on would have done equally well simply by the employment of proper drainage. "If, however, an operation is necessary, I believe the thorascoplastic operation is the best one to employ, but I think that this operation is much oftener performed than is necessary."

This has been the experience, as well of Dr. Dunn's colleagues, as of himself.

Dr. Ferguson closed the discussion by saying that Estlander's operation and also pleurectomy are grave ones, but Schede's operation is much graver. The photographs accompanying this paper show, in the author's opinion, how completely impossible it would have been for further nutrition to get to the surface of the pleura. In his opinion the order in which these various operations should be performed, was that the thorascoplastic should not be performed until Estlander's had failed, in view of the fact that many cases of this latter operation got well, and that pleurectomy should not be thought of until Schede's had been done.

Paper on

ENCHONDRITIS, ITS SURGICAL TREATMENT,

with report of a case and specimens, by B. Merritt Ricketts, M.D. of Cincinnati, O.

THE RATIONAL TREATMENT OF CARCINOMA OF THE CERVIX UTERI, AS VIEWED BY THE GENERAL SURGEON,

by George Wiley Broome, M.D., St. Louis, Mo., and

POST-OPERATIVE INSANITY,

by R. Harvey Reed, M.D., of Columbus, O., were all read by titles.

Dr. Howard Kelly of Baltimore, made some remarks concerning his method of treating

EXTRAUTERINE PREGNANCY.

He spoke of several causes for error in the diagnosis

and treatment of this affection and mentioned that he had mistaken for extrauterine pregnancies dermoid cysts, pelvic abscesses, and small ovarian cysts, all of which he evacuated through the vagina. In his opinion it is rarely necessary to open the abdomen for this purpose.

Dr. Nicholas Senn of Chicago entirely agreed with Dr. Kelly.

Dr. Kelly closed the discussion by advising operators to be careful of the rectum and to keep clear of the uterine arteries and the ureters.

Section on Obstetrics and Diseases of Women.

First Day—May 5th.

The meeting was called to order by the chairman Dr. Joseph Taber Johnson of Washington, D. C., who read an address upon the

Recent Progress in Obstetrics and the Diseases of Women.

He first considered puerperal infection, its causation and treatment, saying that this form of infection had been the cause of much writing and discussion during the year. While something has been added to scientific knowledge of the history and behavior of certain pathogenic germs, the general course of treatment of these cases has been simplified and shortened. In the treatment, the best instrument is the index finger, with which portions of afterbirth or membranes can be removed, using, if necessary, bimanual pressure under ether.

As regards hysterectomy for puerperal infection, it seems to be gaining ground, notwithstanding the opposition of Lusk, Price, and a number of other prominent men in this country and abroad, though the cases, where it is indicated, seem to be very few.

Symphyseotomy, since its revival, has been gaining prominence as a substitute for difficult high forceps operation, craniotomy and Cæsarean section. In perfecting the technic of the operation, the aim has been to deliver the child without laceration of the parts about the urethra, and to so secure the separated symphysis that perfect union would result. In a number of cases, it has come to the knowledge of the writer that copious hemorrhages have taken place from laceration of the vascular tissues about the urethra,

The next subject considered was placenta prævia. Nothing new seems to have been added during the year, except the suggestion that hysterectomy be done for the control of the hemorrhage. The diagnosis is generally not made until the occurrence of the latter.

The surgical treatment for uterine displacements was then considered at considerable length, after which the author passed on to anterior colpotomy, vaginal versus abdominal operations, fibroid tumors, etc.

Dr. Henry P. Newman of Chicago read a paper entitled

A Note on Stenosis of the Cervix as a Factor in Uterine Disease.

He said that twenty years ago this subject was one of the topics of great interest among gynecologists. The literature abounded with learned and exhaustive treatises upon the pathology and treatment of the affection. Notwithstanding the amount of literature formerly written upon this subject, the hundreds of operations recorded by older gynecologists and the nicely adapted instruments that remain as evidences of the reality of stenosis of the uterine cervix, there are some modern authorities who deny the existence of this affection as an anatomical fact. Stenosis was defined as a narrowing of the caliber of the canal, and may be situated at the external os, the internal os, or may include the whole extent of the canal. This condition causes sterility and dysmenorrhea by offering a mechanical obstruction to the entrance of the fecundating element, and by preventing the free discharge of the menstrual fluid.

The author then considered the hygiene of puberty, saying that among the higher educational circles there is already a tendency to demand for girls the same physical advantages that are in vogue in our boy colleges. In our rapid transition from childhood to maturity, the activities demand full general nutrition and conservation of the entire physical constitution. But at this period, the growing woman is pushed to her utmost to support the intellectual and emotional faculties. When the first corset is put on, the growing body is constricted and deprived of the necessary freedom of respiration and circulation. In the radical changing of these conditions lies the rational basis of the treatment of cervical stenosis.

Dr. Sellman of Baltimore, said many young women suffered month after month from painful menstruation, due to retained menstrual fluid. At the last meeting, he spoke of curetting these cases, believing that we accomplish very little oy dilatation. He reams out the diseased membrane or dense fibrous tissue with reamers of different sizes, according to the individual case.

Dr. Stone failed to see why Dr. Sellman's reamer was any better than a curette in skilful hands.

Dr. Hall of Cincinnati, said if we expected to cure cases of dysmenorrhea by dilation of the cervix, or by the reaming out process referred to, making the canal larger, we would be mistaken in our results. He could see how curetting the necessary amount of cervical tissue to leave a large opening might possibly result in a worse condition than would follow dilatation of the cervix.

Dr. I. S. Stone of Washington, D. C., read a paper entitled

How to Remove Pus Tubes Without Rupture.

He illustrated the method by exhibiting a diagram showing the application of clamps to uterine and ovarian vessels before enucleation from the anterior surface of the abscess wall. He summarized the application of this method as follows: It gives more space for careful enucleation. The larger blood supply is tied off before enucleation begins, and no severe hemorrhage can occur during or after the operation. Smaller silk or catgut can be employed, as no *en masse* ligatures are used. If rupture is avoided, there is no need of flushing or drainage. It facilitates enucleation by affording another point of cleavage, namely, from anterior surface of the pus sac. It facilitates exsection of the uterine cornua.

Dr. Stone exhibited a huge pyosalpinx, nearly nine

inches in circumference and fourteen inches in length, which he had recently removed after the manner described in his paper.

Dr. W. G. MacDonald of Albany, read a paper upon

THE PRESENT STATUS OF ECTOPIC PREGNANCY.—A SURGICAL DISEASE.

He said the surgery of ectopic pregnancy is mature rather than old. The pathology and principles of treatment are already established. Yet women are dying every day from ruptured ectopic pregnancy with no effort being made to rescue them, because the condition is not recognized during life. The reason lies principally in the fact that much of the literature has been controversial, abstract, and involved. Pathology and methods of treatment have obscured the most important general topics of clinical history and diagnosis. Favorable results are more desirable than fine pathological distinctions, or beautiful frozen sections. All that is needed to complete the chapter of ectopic pregnancy in the history of surgery, is a living appreciation of its importance by the general practitioner. Such a condition obtains in appendicitis is generally understood and establishes the practice. What is required is a primer on ectopic pregnancy, direct in pathology, clean in diagnosis, and definite in treatment. Such a compend may not be absolutely true in all its statements, probably will not be, but it states general truths, the basis of action. The more descriptive pathology is involved by the expression of opinion and of contentions, the less it is likely to create distinct conclusions. There is no symptom pathognonic of ectopic pregnancy at any period of its history.

Diagnosis only follows careful study of the clinical history, and painstaking physical examination. There are two general propositions which should be generally appreciated in the diagnosis of ectopic pregnancy. First: Any woman who, during her child-bearing period, presents herself with symptoms of disease of the organs of generation, of recent origin, either new or entirely different from those heretofore experienced, if associated with any of the early symptoms of pregnancy, demands at once a careful examination. Second: Abdominal pain, either continuous or intermittent (colic) is always an important symptom and requires the fullest investigation as soon as the complaint is made. Anodynes, without examination, are a too frequent source of death in abdominal diseases.

The treatment of ectopic pregnancy is surgical. Exceptions are to be decided by the consultant or operator. It is to be undertaken as soon as a diagnosis is established. Much sentiment has been wasted and many valuable lives sacrificed in order that a deformed or a paralytic child might arrive at a period where there was a little hope that it might live after delivery. Many cases are emergency surgery and require immediate operation.

All cases of rupture in the interstitial variety belong to this class. The first conditions to be met in operation is the immediate and complete control of hemorrhage. The other steps may be completed more deliberately. Here, as elsewhere, every effort is to be made to close the abdomen after the complete removal of the diseased gestation sac, ruptured Fallopian tube, blood and placenta. Ideal conditions seldom present themselves. A rational conservatism in the conservation of the patient's blood and the prevention of shock will often lead to the employment of expedients, such as suturing the gestation sac to the incision or the use of gauze tamponade, with secondary suture. Saline transfusion either direct or intermediate is more valuable than cardiac stimulants, in the treatment of shock with hemorrhage.

Complete tubal abortion, if diagnosticated, will seldom call for surgical intervention. The fetus is expelled into the abdomen, dies from the rupture of its membranes and hemorrhage, and is absorbed. Many broad ligament pregnancies get well under a purely expectant plan of treatment. There is no hope of convincing the few remaining advocates of electricity of their error, and admonition does no good. The report of seven personal cases illustrating the different conditions met in the disease concluded the paper.

Dr. Joseph Price of Philadelphia followed with a paper entitled

SYMPTOMS, DIAGNOSIS, AND TIME FOR OPERATION IN RUPTURED TUBAL PREGNANCY.

The occurrence of tubal pregnancy is regarded in widely different light by the theorist and the surgeon who has learned to deal with it practically, and who has accordingly come to understand the manifold directions in which speedy disaster may swoop down upon unfortunate women subjected to this calamity. As to the causes of aberrant gestation, we are to consider them both as anatomical and moral. They may have their origin in anatomical loss of structure, or in perversion of function, such as absent ciliary motion in the epithelium, or in absolute disease of the tube, or in the fright of illegitimate conception. Causation can rarely be determined with certainty; there are many agencies which operate to produce the trouble. The character of the attack, the whereabouts of the patient, her employment, are always interesting considerations.

Ruptures with large effusions are easily recognized upon examination. The finger detects an ill-defined, boggy tumor, the uterus enlarged and posterior, or pushed well to one or the other side. If the rupture is quite recent, it may be difficult to define a tumor of any character; there is simply a feeling of general resistance. In examinations made one or two days after rupture, it is easy to define the irregular, boggy tumor, also to locate the uterus, determine its size, position, and mobility.

Dr. Price is convinced, fortified by his own experience, counting now 128 cases with five deaths, that the operative treatment is the only one to be considered. He is fully satisfied that these pregnancies are rarely in the broad ligament. He regards the chief danger of the operation, the hemorrhage. If the patient is found so weak as to render operation an almost certain failure, he resorts to salt water transfusion in order to restore the arterial tension. Rupture with fatal hemorrhage is the most frequent termination; pyemia, septicemia, and peritonitis are much rarer. Basing his conclusions upon his own clinical experience, he holds to tubal origin and intra-peritoneal

rupture, and that all that follows tubal rupture is within the pelvis and peritoneal cavity, and not within the leaflets of the peritoneum forming the broad ligament.

Dr. Eastman of Indianapolis related a case where a physician tried to kill a fetus by electricity and failed. When the patient was *in extremis* she changed physicians. On opening the abdomen Dr. Eastman found a sac containing a living child in an advanced gangrenous condition, which he removed. He believes all extrauterine pregnancies are primarily tubal.

Dr. Reid of Cincinnati has seen cases in which the primary rupture has occurred in the broad ligaments with definite extension of the tumor inward and not upward, although its upper margins could be clearly outlined. The tumor became stationary and finally disappeared.

Dr. Baldwin of Columbus had eight cases of ectopic gestation within the last few months, which were operated upon early and recovered. The subject was further discussed by Drs. J. C. Carpenter, M. B. Ward, and J. H. Letcher.

Section on Neurology and Medical Jurisprudence.

First Day—May 5th.

Dr. T. D. Crothers of Hartford, Conn., the chairman of the section, presented the usual address. He commented upon the growing importance of neurology, and the legal relations and possibilities constantly growing out of present conditions, and spoke of the numerous publications on this subject during the past year. Literally, a new field of medicine is coming into prominence. Neurology is a general topic to be studied by both the specialists and the general practitioner. Dr. Crothers thought the great error in medical training to-day is, the the failure to teach how to observe accurately and how to estimate and compare the results of observation, and this applies particularly to neurology. Preventive medicine, the germ theories, the mysteries of chemical physiology, and all the vast range of "new lands" which are opening up before the student, are insignificant compared with the unknown power of mind, brain force, and what is called nerve energy. The present treatment of crime, insanity, and drug manias by legal methods, has not kept pace with the march of science, so that it is no wonder that expert testimony has fallen into disrepute. The time has come for every student of medicine to assist in clearing up the realm of mystery and superstition, relative to the mental phenomena of neurology. When neurology comes into general science, when jurisprudence becomes an exact study founded on certain definite facts, then the injustice and odium of the present will pass away. Dr. Crothers said that the one central fact which would never be forgotten is, that all nerve phenomena and brain activities are the operation and manifestation of fixed and definite laws.

Dr. J. T. Searcy of Tuscaloosa, Ala., read a paper entitled

Intoxication and Insanity.

He limited the meaning of the word intoxication to the injurious effects on the cerebrum of toxic agents present in the circulation, the symptom of intoxication being those that belong to the brain, this organ being exceeding sensitive to the action of certain agents. The exceedingly soft colloidal character of the functionating central parts of its nerve cells and fibers render them more sensitive to some agents. The nervous system may be divided into sensating and non-sensating structure. Sensibility in the human being is carried to such a degree of centralization that the cerebrum is practically the only sensorium. This physiological fact gives ready explanation to many of the symptoms of intoxication. The word "insanity" is more properly a popular or a legal term than a medical one, meaning that the person has reached such a degree of aberrant conduct that he has to be restrained. It indicates an extreme degree of cerebral defectiveness, there being other grades of impairment above the insane level. Cerebral intoxication arises in the person according to the character of the agent and the particular brain; that is, according to the toxin and according to the abnormality or idiosyncrasy of the particular brain. Toxins such as ptomaines, leucomaines, and other toxic albuminoids, arise from the disintegration of disease in the system besides which there are natural waste products which if retained prove highly toxic. Microbic disintegration of cerebral structure proper is not often seen. Diseases affecting the general system, like the exanthems, fill the circulation with toxins. Some brains being very sensitive under these conditions. Cerebral intoxication from disease in different organs of the body, varies with the organ. The effects of alcohol generally begins in the cerebrum. We may very correctly suppose that whenever we arrest or abate pain with a toxic we do it by hardening the axis cylinders of nerve lines, or the central parts of nerve cells, in this way preventing or lessening their functional motion.

Dr. Frederick Peterson of New York, thought the chief means of treating these cases, which arise from auto-intoxication, as by a properly regulated diet, milk, vegetables, and so on, by washing out the stomach and intestines with hot water, and by the use of certain antiseptics like salol, given in pretty good doses two hours after meals.

Inebriety in the Etiology of Insanity,

by Dr. I. N. Quimby, Jersey City, N. J., was read by title.

Dr. G. W. Drake of Chattanooga, Tenn., read an article entitled

Man's Brain and Mind: The Former Sometimes Insane, the Latter Never.

He said a sane brain is one in which all its cells and cell derivatives—fibers and other material substances—are in a normal state chemically, physically, and vitally. Chemical analysis of the different parts of the brain is not alone sufficient to enable the neurologist to judge of its sanity, nor is microscopical examination adequate, because neither will reveal the relative position of molecules in a cell or atoms in a molecule. Man is a *triune* being, consisting of a material *ego*, a sensible *ego*, and an intellectual *ego*, body, spirit, and mind. Dr. Drake said he did not believe in the existence of mental diseases, or dis-

eases of the sensible *ego*, disease being rather a disarrangement of matter in the structure of one or more cells of the body. The sensible *ego* is always ready to exercise its faculties in the various brain centers, but it is necessary that the peripheral and central organs must be in health in order that the sensations may become conscious, normal impressions. There is a material basis for every pain and every subjective symptom of disease or discomfiture. Brain culture, as a physical science has not received proper attention. The cerebral centers should be duly exercised in order to enhance their capacity, and brain sanitation is conducive to sanity.

The mind is never insane. Its brain machine may break down and need adjusting, but the mind cannot be injured by traumatism, auto-intoxication, or bacterial toxins. There is no difference in the members of the human family, Hottentot, Mongolian, or European: as to their minds, the difference is only in the structure of their brains.

The chairman named Dr. Harold N. Moyer and Dr. Elmer S. Pettijohn to fill the vacancies on the executive committee.

A NOTE ON THE PATHO-MENTAL EFFECTS OF DEGENERATIVE HABIT

was read by Dr. H. S. Drayton, New York City. He referred to Dr. Henry Maudsley's statement that a man is "By no means hopelessly chained down by the weight of his inheritance, for there is something else that makes fate and that is education."

Habits, however acquired, produce in time conditions in mind and body that of themselves reflect a healthful or injurious nature. If vicious habits are persisted in they accomplish alterations in the substance and relations of the cerebro-spinal organism that are abnormal and degenerate. The form and constitution of the brain bear a particular relation to mind capacity and character. Though habit has its co-ordinate factors in the cerebral substance where molecular changes are produced with facility and effects correspondent to the duration of the habit. Dr. Drayton referred to Dr. Elmer Gates' experiments on the color sense of dogs, proving that the forced exercise of that sense for a period had a result in decided increase of brain tissue in the color area.

Conversely, disease of mind faculty is attended with declension and disease of the cell elements of the co-ordinate center and decline in strength. The disturbances of function wrought by the practice of taking alcoholic beverages daily belong to our common stock of knowledge, and represent generally, or analogously, what of nerve injury is done by toxic narcotics as a class, depressing the vital tone of every organ of the body. The president of this section, after years of critical observation, has said: "The tendency in nature being toward the maintenance of the perfect type, we may look for an endowment of new normal tissue where all the conditions are favorable, and under such circumstances a cure, or what is popularly called 'reformation,' takes place."

Dr. Charles H. Hughes of St. Louis, Mo., opened the discussion on these papers. He thought it rather unnecessary to emphasize the essential difference between the brain and the mind, and considered it settled that the consideration of the latter was exclusively within the realm of metaphysics, as science deals only with matter.

Dr. W. H. Burr continued the discussion, expressing his approbation of Dr. Searcy's paper and Dr. Hughes' remarks. He said that, in his opinion, in the majority of cases of hypochondriasis there is at the bottom a pathological condition, often a state of auto-intoxication.

Dr. Sanger Brown referred to the recent advances which have been made in the conception of the neuron, owing to the investigation of Dr. Berkeley of Johns Hopkins University, who experimented upon dogs, feeding them excessively with alcohol for seven or eight months, until many of them died of convulsions. Definite changes in the body of the neuron were found. Every safeguard was used to prevent the experiments from giving misleading results.

Dr. Searcy also referred to Dr. Berkeley's experiments at Johns Hopkins.

Dr. Kleinsmith of Washington, also discussed the papers.

Dr. Frederick Peterson of New York, presented an article on the

MEDICAL AND SURGICAL TREATMENT OF EPILEPSY.

He referred favorably to the so-called opium bromid treatment of Flechsig, having found it of use, especially in old and obstinate cases. In epilepsy, resulting from auto-intoxication, much benefit may be obtained by the regulation of the diet. Dr. Peterson spoke further of the moral treatment of epilepsy and the unfortunate position of the victims of this malady, reared in idleness, neglected in mind and body, their only recourse being almshouses and insane asylums. He mentioned the Craig Colony in New York, with accommodation for three hundred patients. The surgical treatment of epilepsy he summed up as follows:

(1) In about one per cent. of all cases of epilepsy an injury to the head will be found to be the original cause.

(2) In a much larger percentage, an old meningeal hemorrhage, congenital or acquired in infancy, giving rise in addition to the epilepsy, to various degrees of paralysis, idiocy, or other cerebral symptoms, and presenting on examination atrophic, sclerotic, or cystic sequelæ to the primary lesion, will be found to be the cause.

(3) In the present state of our knowledge and experience, those cases due to meningeal hemorrhage should not be operated on at all.

(4) In the very small number of cases having injury to the head as a cause, the epileptic habit is so strong and the changes in the brain usually so old and so deep-seated, that operation, as a rule, does not cure, and only seldom permanently diminishes the frequency of attacks.

(5) Of miscellaneous traumatic cases where surgical procedure seems justifiable and is undertaken, a cure may be reasonably expected in perhaps four out of every hundred cases operated upon.

(6) The removal of a cicatrix from the cortex supposed to be the epileptogenetic nidus will naturally be followed by the formation of a new cicatrix in the surgical wound, and is scarcely a defensible procedure.

(7) The most recent the injury the greater will be the promise of lasting benefit. If a hundred cases of epilepsy could be selected in which the trauma dates but a few months back, trephining and ablation of the morbid tissues would doubtless prove curative in a very large percentage of cases.

Dr. Campbell of Knoxville, Tenn., in discussing Dr. Peterson's paper, deplored the fact that there was no satisfactory arrangements for the State charge of epilepsy and urged the profession to make vigorous efforts to this direction in order that other States might follow the example of New York and make similar provision for the care and education of this class of patients.

Dr. John Punton of Kansas City, Mo., said that he was entirely in accord with Dr. Peterson's views as to surgical procedure in epilepsy and that the cases in which it was of advantage were very rare.

Section on Children's Diseases.

First Day—May 5th.

The section was called to order by Dr. A. C. Cotton of Chicago, who read an address entitled

has the milk laboratory come to stay?

Dr. Cotton stated that in the selection of the subject upon which to address the Section he had been guided somewhat by the recent interest taken in the elaboration of infant food. There are three quite defined classes of infant feeders: (1) Those who regard the infant as belonging to the carnivora; (2) Those who would place the nursling of the human species among the granivora, and (3) Those who early place the young in the omnivorous class. Says one theorist, "Raw milk is poison"; another "Bottled milk is indigestible"; another "Starch is indigestible"; still another "Cereals are unnatural."

Again, "cows' milk, even if freed from pathogenic bacteria, is ill adapted to the stomach of the human infant because its constituents do not bear the same proportion to each other as in breast milk." So we attempt to render the proportions of the constituents the same as in the natural product of the maternal breast. Along this line the addition of lime water the use of dilution and of the separation and reunion in exact proportions of the constituents has been tried. Still the infants have continued to die. But I believe the milk laboratory has come to stay. The advantages lie in the direction of more exact manipulation, greater precision and accuracy in the keeping of records. We are securing through these laboratories in Chicago very gratifying results. In the milk laboratory the cerealists find the best facilities for testing the value of their theories. The experiments of Dr. Leeds, of Hoboken, have stimulated an effort to still further eliminate the casein without reducing the per cent. of proteid substance. It seems to have been successfully attempted by replacing a large part of the rejected cow proteid with egg albumen. At first it was thought that egg albumen would be coagulated when Pasteurization was attempted, but this difficulty has not proven insuperable.

Dr. C. G. Slagle of Minneapolis, read a paper upon

diagnosis in disease of children.

The author reviewed largely the subject of diagnosis in general since it is unsatisfactory otherwise to discuss diagnosis in this special department. The queries arise: First, What is the import and advantage of diagnosis? Wherein its intricacies, and what relation does it sustain to other branches of medicine? Second, What special feature does it possess in its relation to diseases of early life? Third, What is the present status of this department of our art as compared with the past? Fourth, Can it be facilitated or any way rendered more accessible and comprehensible to our students and young practitioners? Fifth, Is there a demand for a treatise on the diagnosis of the diseases of infants and childhood, general and special, medical and surgical? Many men never make good diagnosticians, and many good diagnosticians frequently make mistakes in diagnosis. His definition of a good diagnostician would be one with the faculty of recognizing diseases so as to locate and name them with facility by the correct interpretation of their pathological and clinical symptoms, and thus be able to differentiate one from all others. The man who can render a correct diagnosis at his first examination of the child in four-fifths of his cases, is a fairly good diagnostician. The practitioner will be successful in pediatrics precisely in proportion as he has given attention to all other parts of the art. But many ailments of children simulate each other so closely it is difficult, even impossible, to render a correct diagnosis. Many affections of the young differ from the same affections of the adult, in their clinical symptoms and sometimes in their anatomical aspect. And not only do diseases hybridize in the young, but there are many diseases peculiar to that period.

Dr. J. A. Larrabee of Louisville complimented the paper and spoke of the importance of the subject. Those who make instantaneous diagnoses often make very grievous errors. Although men may differ in their diagnostic capacity, as in other capacities, still "genius is only another name for hard work." We must use all our senses and all available knowledge, and even then we will sometimes fail to make a correct diagnosis. Often much may be accomplished by a careful study of the face of the child, which frequently is very expressive.

Dr. Samuel E. Woody of Louisville concurred with the essayist as to the many difficulties of diagnosis in children. These may be overcome only by the greatest amount of tact and patience. But diagnosis is not more difficult in children than in adults. The thinner chest and abdominal walls of the infant, as well as the expressiveness of the countenance, tend to make the diagnosis easier. In the employment of the Rontgen photograph, the thinness and translucency of the tissues in the child is an advantage.

Dr. J. A. Larrabee of Louisville followed with a paper upon the

pediatric therapeutics, as proven by experience.

The paper opened with the quotation: "Prove all

things; hold fast that which is good." Widely different effects may be obtained from the same drug in different doses. In children, the best are usually to be obtained from small doses, frequently repeated. In the discovery of new remedies, we have been more successful, reasoning by synthesis than by analysis. The author condemned the use of the polypharmic compounds, emphasizing the importance of the use of simple prescriptions. At any rate, the prescription should be the creation of the physician, and not of the pharmacist. The compound prepared by the manufacturing chemists too frequently contain elements which are directly opposed to each other in action, or elements which are not indicated in the same case, or elements which soon become non-effective. Too frequently they are simply shotgun prescriptions.

The author had obtained good results in entero-colitis by the use of 1–100 grain arsenite of copper in a four ounce solution, using a teaspoonful every fifteen minutes. One-fourth grain tartar emetic in a pint of water teaspoonful every half hour, controlled cerebral symptoms when the toxic dose would have increased discomfort. In acute tonsilitis, small frequently repeated doses of aconite and belladonna had proved valuable. Perhaps one of the most pernicious outgrowths of polypharmacy is the compounding of the therapeutic incompatabilities. The author gave a number of illustrations along this line. He believed the use of antiseptics good practice. Thus, the essayist had obtained good results with listerine and borolyptol in infants with lactic acid fermentation in the stomach as well as in children with putrefactive changes in intestinal ingesta, after removal of ingesta by enema and purgation. Guiacol has proven to be the ideal intestinal antiseptic. Indeed the author believes this agent is the effective one in the so-called Woodbridge treatment. However, in enteric diseases it is a better plan to prevent the complications than to trust to their treatment when they appear.

Dr. Larrabee described the coal-tar products, antipyretics, as indispensable agents in infantile therapeutics. The *antitoxin diphtheriticum*, while not a specific for diphtheria, is an agent of great value. Asafetida in the form of the tincture, combined with milk of magnesia is an excellent remedy for the distressing colic, intestinal acidity, and constipation. Also its administration by the mouth and discharge per anum is of diagnostic value in suspected obstruction or intussusception. Also it is valuable in the sinking stages of pneumonia or capillary bronchitis. Emetics have fallen into disuse while the use of the stomach tube has grown in favor. Non-depressing emetics are of great value in warding off atelectasis in infantile bronchitis and pertussis. Turpeth mineral has supplanted all other irritant emetics. Systemic or centric emetics are out of place in such instances. The syrup of ipecac should be discarded as slow and uncertain and ineffectual. Besides the syrup is objectional.

Hydrotherapy is endorsed by all physicians, but practised by only a few. This method of treatment is of very great value, and should be more frequently resorted to. The wet pack at 98½ degrees is preferable to immersion. Often the best results follow the long-continued use of the wet pack. In bronchitis and pneumonia, water is the only expectorant indicated. Belladonna is best given in small, even minute doses, repeated at frequent short intervals. It has thus proven a valuable remedy in the low stages of fevers, cholera infantum, and pernicious intermittents. As a stimulant to the respiratory nerve centers, it is useful in the sinking spells of pneumonia. A number of cases of enuresis have been reported cured by atropia.

Dr. C. G. Slagle of Minneapolis, endorsed the paper, adding emphasis to everything the author said.

Dr. Henry E. Tuley of Louisville, thought the theory of the antitoxin is to neutralize the products of the germs, and it is our duty to get rid of the production of the germs, locally if possible. We are not justified in abandoning the use of the local treatment when we use the antitoxin. The use of the stomach tube is usually more effectual in infants than the use of emetics, when it is desired to empty the stomach.

Dr. I. N. Love of St. Louis, discussed the paper at some length, agreeing with the author almost entirely. He especially emphasized the use of water in diseases of children.

Section on Practice of Medicine.

First Day—May 5th.

The meeting was called to order by the chairman Dr. Wm. E. Quine of Chicago who read an address upon

The Advances in Therapeutics During the Year.

An epitome of the literature and some observations of the writer in relation to the therapeutic effects and *modus operandi* of bone marrow led him to the conclusion that the agent was of undoubted value in relation to the treatment of ordinary simple anemia and chlorosis and in cases of anemia of the more intractible kind. There is not conclusive proof that it has any therapeutic power beyond that which can be fairly ascribed to the influence of a readily assimilable organic compound of iron. We have no knowledge whatever that enables us to understand how it is possible for this agent to produce a curative effect in cases of progressive pernicious anemia, leukemia, and kindred disorders. It cannot act in the manner of an animal extract like that of the thyroid gland or suprarenal bodies which supplies a deficiency that is occasioned by incapacity of the organs alluded to, for in pernicious anemia and leukemia there is not atrophy nor inactivity of bone marrow. On the contrary this is hypertrophied and over-active. Moreover, evidence is wanting that bone marrow is a secretion or that it contains any ingredient which stimulates its own production. The subject is still *sub judice* and requires many careful observations to establish conclusions on solid grounds.

Fourteen cases of Addison's disease treated with the adrenals of lower animals, mostly those of sheep, are now on record. The favorite preparation appears to be a glycerite of the minced organs, given with a degree of freedom amounting to from fifteen grains to three drams of these organs daily. In about one-half of the recorded cases, improvement has been noted, and in a few of them the improvement has been very striking, but we are lack-

ing in information as to the stability of it. Quite as good evidence is furnished by medical literature that adrenal extract does injury in some cases of Addison's disease, as that it is productive of benefit in others. It is not difficult to understand in case of disease and incapacity of the supra-renal bodies, how the artificial supply of their peculiar products may make an important impression of a temporary kind; but it is not obvious how in case of advanced disease of those organs, the administration of sheep's adrenals for a few days or weeks, can make the patient so sound and well as to enable him to thrive ever after without the assistance of his own organs.

The treatment of typhoid fever was introduced by a presentation of the claims of Woodbridge of Ohio, and Thistle of London, in relation to their ability to abort the disease, or at least effect a cure of it, in every instance in which the treatment is permitted to have a fair trial. The improbability of the correctness of these claims was pointed out upon the basis of established knowledge of the etiology and morbid anatomy of the disorder; and it was shown that long before the physician has opportunity to prescribe his first dose the bacilli of the disease had already, to some extent at least, penetrated the walls of the bowel and migrated to remote parts of the body. It was freely conceded, however, that by processes of purgation and intestinal antisepsis meteorism could generally be obviated altogether, or if already present, dispelled. It was also conceded that under treatment of this kind, instituted early, the evacuations were never fetid; or if fetor already existed, it could, with considerable uniformity, be corrected in the course of a few days.

The writer also directed attention to the fact that the invasion of tissue and elaboration of toxins by the microorganisms of typhoid fever were not completed in a day, but were continuous and occupied many days. Hence it was plainly within the limits of rational probability to lessen the degree of concentration of infection in the intestinal structures, and the consequent liability to the destruction of them, as well as the degree of general toxemia and its attendant dangers, by prompt and sustained effort in the direction of preventing or restraining the process of continuous recruital from the lumen of the bowel. The author was of the opinion that the plan of treatment has a rational foundation, and is of real utility, but suspected that his friend, Dr. Woodbridge, has been led to erroneous conclusions by reason of the extraordinary mildness of the typhoid fever which has been prevalent during the last two or three years. The address excited a very heated discussion, especially upon the treatment of typhoid fever, and very strong and extreme positions were taken by the speakers on each side of the question.

General Session.

Second Day—May 6th.

The Secretary read the names of the members of the Nominating Committee.

An invitation from the Louisiana State Medical Society was read, inviting the members of the association to attend the next meeting to be held in New Orleans.

A motion expressing appreciation prevailed.

Vice-President LeGrand appointed the following committee to consider the recommendations in the president's address: Drs. N. Senn, Alonzo Garcelon, Jos. Taber Johnson, E. S. Lewis, and Dudley S. Reynolds.

On motion of Dr. Cochran of Alabama, the committee on National Department of Public Health was increased so as to include one member from each State.

Section on Diseases of Children.

Second Day—May 6th.

The entire time of the meeting was consumed in a discussion of the antitoxin treatment of diphtheria.

Dr. Elmer Lee of Chicago, read a paper in which he followed quite closely the statistics and arguments of Dr. Winters of New York in opposing the use of antitoxin. Horse-serum poisoned by germ culture has no natural place in the human blood.

The red blood-corpuscles are dissolved whenever horse-serum comes in contact with them. On the contrary, however, the fluid which patrols the entire body should be strengthened rather than decomposed and disorganized by the addition of morbid matter.

Dr. J. W. Stickler of Orange, N. J., concluded from his experience that when the heart's action is fairly good, when the system has not been seriously impaired, when the urine shows little or no albumin, antitoxin, judiciously used, is likely to benefit the patient, but when there is great depression of the vital forces antitoxin is contraindicated.

Dr. Louis Fischer of New York, emphasized some practical points in the combined effects of antitoxin and intubation, with special reference to infant feeding in malignant diphtheria. He explained the sudden deaths following injections of antitoxin as due to accidental entrance of air into the blood-vessels. He urged abundant and proper nutrition by stomach and by rectum.

Professor Edwin Klebs, late of Zurich, was present and brought forward in support of the antitoxin treatment the fact that control animals die, whereas protected animals injected with the same dose of the poison recover. He affirmed, however, that the immunizing power of the serum had not been demonstrated, but as to the curative influence of antitoxin the great mass of statistics agree that it is successful. He had found chinosol the best antiseptic to preserve the serum from the presence of other bacteria.

Dr. W. E. Cassellberry of Chicago, said that the use of antitoxin had reversed, his statistics and reduced a mortality of seventy-five per cent. to twenty-five per cent.

Dr. J. A. Larrabee of Louisville, considered the germ theory a germ fact. He had seen four cases die who he believed would not have died had they not used antitoxin, but he had also seen twelve cases survive that would have died without the antitoxin. He believed in vigorous sustaining treatment whether antitoxin was used or not.

Dr. Rose of Kansas had passed through an epidemic of diphtheria in which he and his partner had treated fifty cases with the antitoxin, and all recovered. In none of them had there been any irritation at the point

of injection; in only one did erythema occur. DR. THOMSON of Albion, Mich., DR. BELL of Atlanta, Ga., DR. HODGKINS of Connecticut, and DR. D. C. WILSON of Ohio, all gave favorable testimony from their experience confirming the value of the antitoxin treatment.

GENERAL SESSION.

THIRD DAY—MAY 7TH.

Meeting was called to order by the president. DR. NICHOLAS SENN of Chicago, delivered the

ADDRESS ON SURGERY,

For which see page 507.

It was decided to hold the next meeting in Philadelphia, and Dr. Nicholas Senn of Chicago, was unanimously elected president for the ensuing year.

ASSOCIATION OF AMERICAN PHYSICIANS,

Eleventh Annual Meeting, Washington, D. C., Thursday, April 30, 1896.

(Specially Reported for THE MEDICAL NEWS.)

OPENING SESSION.

At 11 o'clock the meeting of "The Immortals" of our American profession was called to order by the President, A. JACOBI, M.D., who after the minutes of last year's meeting had been approved as printed, proceeded to deliver his brief but pointed and graceful address. (See pp. 511).

His keynote was "The Unity of Medicine as of the Church."

Notice was then given of the submission of an amendment to the constitution increasing the limit of membership to 125 instead of the present 100.

DR. BUSEY, of Washington then took the floor under the heading of special business, and in an earnest speech urged upon the Association the desirability of memorializing Congress against the passage of the pending bill practically prohibiting vivisection in the District of Columbia.

The greatest danger lay the indifference of the general medical profession and the foolishly weak letters written by individual medical men in favor of a modified form of of the bill. Huge memorials from sentimental men, women and clergymen, were pouring in from every quarter, and but little organized opposition is in evidence. A strong committee of five consisting of Drs. Welch, Vaughan, Pepper, Edes, and Theobald Smith was appointed by the chair to draft a memorial.

The formal program was opened by DR. F. H. WILLIAMS of Boston in a short paper upon

THE ROENTGEN RAYS IN PHYSICAL DIAGNOSIS.

He presented to the Association an ingeniously simple instrument, the fluoroscope, by means of which the chest could be examined with the X-rays.

By means of this the upper border of the liver can be made out as it rises and falls in respiration, also the outlines and fact of movement of the heart and outlines of the spleen, all of which corresponded to tracings of the organs mapped out upon the surface by percussion.

In three very interesting cases, one of pneumonia and two of pulmonary tuberculosis darker areas could be distinctly made out, in one at the left base and in two at the right apex, which corresponded in each case to the area of dulness.

In the neck, the anterior line of the spinal column can be seen, and the rings of the trachea, separated by a lighter streak, corresponding to the esophagus, which permits the hope that foreign bodies in the latter, could be thus located.

As a contribution to the discussion, Dr. Sternberg read a letter from Dr. J. H. Stone, U. S. A., of Leavenworth, Kan., describing a series of experiments with the X-rays upon cultures at various pathogenic bacteria, with absolutely negative results.

DR. WILLIAMS remarked that like trials had given identical results in his hands.

DR. OSLER asked whether gall-stones could be detected by the rays?

DR. B. K. RACHFORD of Cincinnati, followed with a paper upon

LEUCOMAIN POISONING (CONTINUED),

which will appear in the NEWS.

DR. VAUGHAN asked what tests were relied upon for the detection of xanthin and paraxanthin, and if observations had been made as to whether leucocytosis was increased in these cases? The nuclei of leucocytes being now regarded as the chief source of such bodies.

DR. OSLER congratulated Dr. Rachford and also the association upon the careful study which was being made of these interesting substances in this country, as they were attracting much attention in Europe. He also asked whether the presence of Neisser's granules about the nucleus of the white corpuscles had been studied in these cases. These are found so invariably present in the various uric acid states and true gout as to be now regarded as almost pathognomonic of these conditions.

Other suggestions were made by DRS. BAUMGARTEN, PUTNAM, MELTZER, and DA COSTA.

In closing the discussion, DR. Rachford replied to Dr. Vaughan that the chemical tests relied upon were those given in the text-book of the latter, known as the "yellow residue" and "green scum" tests, but that the physiological test by injection into animals ranked highest. Both, however, corresponded in all of his cases.

In reply to Dr. Putnam's question, he stated that urinary examinations in the interval between the attacks gave no trace of xanthin, nor was it ever present in ordinary epilepsy.

DRS. V. C. VAUGHAN and GEO. D. PERKINS at Ann Arbor, Mich., then presented a communication upon

A TOXICOGENIC GERM FOUND IN ICE CREAM AND ITS PRODUCTS.

In August, 1895, they were furnished with some ice cream which had poisoned some fifty people in Northern Michigan and about a month later with some cheese which had produced severe nausea, diarrhea, and prostration in twelve persons. Upon examination the same bacillus was found present in both specimens. The symptoms pro-

duced in both cases were almost identical and in neither did any deaths result. The germ was thoroughly studied and the results given in detail. Most interesting among which were the facts that its growth in milk was accompanied by a *pleasant* odor of butyric ether; that it grows freely upon all fruits and vegetables, potassium salts are necessary for its growth, it resists prolonged freezing but succumbs to a heat at 58° C.

It does not produce any effect upon cats when given by the mouth in enormous doses, though rapidly fatal when injected. Experiments were conducted upon rats, mice, guinea-pigs, and dogs.

They were not successful in isolating the chemical toxic produced at the bacillus, but believe it to be nearly identical with tyrotoxicon and probably a proteid.

By some mistake a strong solution of the toxin was put into a bottle labeled "Nuclein Sol.," and ten minims of it injected into a human subject. Severe vomiting, with profound depression, followed by delirium and coma, rapidly ensued, but the symptoms happily passed off in about twelve hours. It was, however, nearly three days before the patient had recovered sufficiently to walk alone. The singular fact being that this dose produces no appreciable effect upon a guinea-pig, showing the human subject to be vastly more susceptible to this poison.

A spirited discussion followed.

AFTERNOON SESSION.

DR. SIMON FLEXNER of Baltimore, read the next paper upon

STATISTICAL AND EXPERIMENTAL STUDY OF TERMINAL INFECTIONS.

He asserted that the careful and systematic bacteriologic study of the tissues from the *post-mortem* room was of more importance than mere clinical observations. Bacteria were often found when least expected, and even negative results were not conclusive against their possible presence in other unexplored tissues. In 793 autopsies at Johns Hopkins Hospital, 255 were chronic cases of kidney or heart disease, and in 213 of these bacilli were found in appreciable numbers. Local infections, especially of peritoneum and pericardium, were most common. The organisms were of many species, the pyogenic cocci largely predominating, followed closely by the colon group. Cultures from them proved generally inert in animals on inoculation.

The avenues of infection were various but the most frequent were intestinal lesions. Chronic diseases are important as predisposing factors to bacterial invasion and in most of them death is actually caused by some so-called "terminal infection."

In other words these pestilent organisms will not permit us to even poison or soak ourselves to death, à lá Bright, in peace. Pathogenic bacilli are often present in health but can gain no foothold till the resisting power at the tissues is lowered by disease.

A series of experiments was reported upon the bactericidal power of blood-serum from cases of chronic disease in Johns Hopkins Hospital, compared with that of healthy subjects obtained at surgical clinics. The staphylococcus pyogenes aureus was rapidly destroyed by normal serum, also the cholera and typhoid bacilli, while the serum of cachectic patients was much less active. This bactericidal power of normal serum, though always marked, was extremely variable and a similar property was usually found in the serum of animals exempt from given diseases. Normal serum also destroys the toxins, as well as the bacteria.

DR. STERNBERG quoted experiments showing that placental blood was almost inert against bacteria, and suggested that antitoxins could not pass through capillary coats, and hence might be retained in the blood for long periods. This would explain the long after-immunity in some diseases; in others it is probably due to constant reproduction of antitoxins.

DR. BOND asked whether the number and condition of the corpuscles in the blood used had been observed.

DR. THEOBALD SMITH stated that recent experiments by inoculating animals with weak cultures of bacilli, waiting till some time after their recovery and then killing and examining tissues, had revealed the continued presence of bacteria in the organism as long as fifty days after recovery.

DR. BOLTON expressed surprise at Dr. Sternberg's statement in regard to placental blood, as Ehrlich had proved the transference of immunity from mother to offspring in a number of cases of tetanus, etc.

DR. STERNBERG regarded the immunity in these cases as due to the ingestion of the mother's milk.

DR. BOLTON replied that the same results had been obtained when the offspring were suckled by a non-immunized foster-mother. Both the offspring of an immunized mother reared on non-immunized milk, and the offspring of non-immunized mothers reared upon immunized milk, were alike refractory to infection.

DR. FLEXNER, in closing the discussion, replied that the corpuscles had not been studied, that Dr. Sternberg's statement puzzled him, as placental blood was found antitoxic in eighty-five per cent. of diphtheria cases, and that the tissues of guinea-pigs recovered from typhoid were found by him to contain well-marked typhoid bacilli several months afterward, which supports Lubarsch's findings that bacteria can resist destruction in solid tissues far longer than in the blood.

This was one of the most suggestive and interesting papers of the entire session.

DR. A. C. ABBOTT of Philadelphia, followed with a report of experiments upon

THE INFLUENCE OF ACUTE ALCOHOLISM ON THE NORMAL RESISTANCE OF RABBITS TO VARIOUS FORMS OF INFECTION.

These had been carried on under the auspices of the "Committee of Fifty" upon the "Influence of Alcoholic Liquors as Beverages."

The general drift of the results showed that alcoholic intoxication distinctly lowered the resistance to certain forms of bacteria, but not to others. The former included the whole strepto- and staphylo- group and the bacillus coli. The experiments were also made upon control groups of non-alcoholized rabbits simultaneously. The

practical difficulties of the investigation were found very great. In the first place, rabbits, being highly susceptible to these infections, it was hard to obtain a culture sufficiently attenuated to permit differences to be observed other than *post-mortem* ones, and yet of sufficient virulence to be active in every case. On the other hand, it was difficult to fix upon a "standard" dose of alcohol, which could be relied upon to produce intoxication, individual susceptibilities varying so greatly, as among men, and no satisfactory physical sign of intoxication could be found except that of a staggering gait, which was naturally hard to produce in a quadruped of such abstemious habits and conservative tendencies.

In order to reach this result such massive doses had to be given, as to be the equivalent of twelve to fourteen ounces of absolute alcohol in the human subject, and these were followed by such large and rapid losses of body-weight, as to raise the question in Dr. Abbott's mind, whether they did not lower resisting power, much as starvation would have done. Lastly, no combination, not even with mint, could be invented which would induce the animals to take the drug voluntarily. It had to be administered by a stomach tube, and this, in many cases, sooner or later caused abrasions of the esophagus and stomach, through which secondary infections developed with fatal results. The experiments up to date were reported in some detail, but the writer declared the investigation but partially completed, and that no definite conclusions could yet be drawn. This much could be said with certainty that the normal vital resistance of the tissues against invasion by the streptococcus pyogenes, staphylococcus aureus, and bacillus communis coli, was distinctly and invariably lowered by such doses of alcohol daily. The time of incubation of the virus was shortened and the lesions more marked. The result appeared to be due to the direct effect of the alcohol upon the tissues, as no change, whatever, in them could be detected upon careful microscopic examination.

DR. MELTZER asked whether injecting the alcohol hypodermically or by the rectum had been tried, and thought that the amount of water and green foods in the stomach might cause variations in the result.

DR. ABBOTT replied that neither of these methods had been tried, as the attempt was to reproduce the conditions of the human problem as closely as possible.

DR. H. C. ERNST of Boston followed with a paper upon

THE IDENTITY OF THE STREPTOCOCCI AND A DESCRIPTION OF A NEW VARIETY.

The position was taken that the action of all varieties of streptococci in the human organism was practically the same, due probably to their all producing a similar toxin and that there was hope that a single antitoxin might be developed which would be effective against all of them.

The new variety now introduced to the profession had been obtained from the blood and peritoneal fluid of a case of secondary puerperal infection. The symptoms were characteristic but very severe and death occurred in convulsions upon the thirteenth day. The bacillus presented the usual "strepto" characteristics and reactions, but with certain distinct peculiarities which entitled it to the rank of Streptococcus Aureus Liquefacillus, which had accordingly been conferred upon it.

It was found only feebly virulent in guinea-pigs and rabbits. The paper was illustrated by water-color drawings of cultures.

DR. STERNBERG remarked that there could be no question as to its admission to the strepto group with the rank of a variety, and DRS. ABBOTT and BOLTON also expressed themselves convinced and welcomed it to the ranks of the pyogenic brotherhood.

DR. THEOBALD SMITH of Boston, then read a report of a carefully planned series of ingenious experiments upon

THE CONDITIONS INFLUENCING THE APPEARANCE OF TOXIN IN CULTURES OF THE BACILLUS OF DIPHTHERIA.

The principal factor appeared to be the amount of muscle-sugar present in the culture bouillon which acted mainly by promoting acidity or delaying the development of alkalinity in the solution. His experiments confirmed those of Sprague that the higher the proportion of muscle-sugar, the less the amount of toxin developed. This was illustrated by a series of charts showing "curves" of both substances. Anything above 0.2 per cent. of muscle-dextrose practically inhibited toxin formation, and this proportion varied greatly in the beef of different localities. The sugar acts also by delaying the formation of the toxin to such degree that it can be consumed by the bacilli as fast as formed. In mixed cultures the toxin forms more rapidly because the sugar is destroyed by the other germs.

DR. ERNST and DR. BOLTON asked some questions as to methods of preparing beef for bouillon.

DR. BOLTON'S two papers upon

DIPHTHERIA ANTITOXIN,

though brief and partial, were of great suggestive interest. The first was upon the presence of antitoxin in the blood of normal horses. Attention was first called in this direction by the fact that individual horses varied greatly in the degree of their reaction to diphtheria inoculations. Some animals appeared almost immune from the start. Upon investigation, he had found that out of twelve horses tested three possessed antitoxin in appreciable amounts. These showed very little reaction to the virus until very large doses were injected, but ultimately produced no stronger or larger amounts of artificial antitoxin than the others. Traces of antitoxic substances had also been found in the blood of human subjects, especially in children, and most markedly in convalescents from diphtheria. It soon disappeared, however, from the serum of the latter.

DR. FLEXNER said that these experiments confirmed Fischerl's results, who found traces of antitoxin in the blood in eighty-five per cent. of children examined. The same had been found in goats against cholera.

DR. SMITH added that some horses never produce antitoxin beyond a certain strength, no matter how long the inoculations were kept up.

THE MEDICAL NEWS.
A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXVIII. NEW YORK, SATURDAY, MAY 16, 1896. NO. 20.

ORIGINAL ARTICLES.

LEUKOMAIN POISONING.[1]

BY B. K. RACHFORD, M.D.,
OF CINCINNATI, O.;
PROFESSOR OF PHYSIOLOGY, AND CLINICIAN TO CHILDREN'S CLINIC MEDICAL COLLEGE OF OHIO.

THIS communication is offered as a sequel to the paper on the same subject which I read before this Association last year. At that time I presented the experimental and clinical evidence upon which I based the opinion that leukomain poisoning is a most important phase of auto-intoxication, which may manifest itself in at least three distinct but closely allied clinical types, viz.:

1. Leukomain Headache (True Migraine).
2. Leukomain Epilepsy (Migrainous Epilepsy).
3. Leukomain Gastric Neurosis.

Another year of work in this field has enabled me to separate still another clinical type of leukomain poisoning which I shall call, in conformity with the above nomenclature,

4. Leukomain Asthma.

This form of asthma presents very much the same clinical picture as ordinary bronchial asthma. The attacks, as a rule, come on during the early morning hours, and vary in severity from a simple to the most intense dyspnea. My impression is that this type of asthma is not uncommon, and that it goes to make up a not inconsiderable proportion of the asthmatic attacks which are classified under the comprehensive term, "bronchial asthma." However this may be, I am quite sure that the urine passed during certain of these asthmatic attacks contains a very great excess of paraxanthin and other leukomains of the uric acid group, and that the paraxanthin solution separated from the urine of these cases will, when injected into mice, produce intense dyspnea with the other symptoms of paraxanthin poisoning. The following case is offered as an example of leukomain asthma:

CASE.—A woman, aged sixty, of gouty inheritance and strong neurotic tendency, a number of her family have suffered from rheumatic gout, migraine, and asthma. She and a number of her family have an uncomfortable amount of adipose tissue. For three or four years this patient suffered, at times, from vertigo and shortness of breath without apparent cause. These symptoms could not with any certainty be traced to bodily exertion, nervous excitement, indigestion or any other exciting cause. On February 22, 1895, one of these attacks of dyspnea culminated in a very severe attack of asthma, which continued in paroxysms for five days. During this time a paroxysm of intense dyspnea would occur, as a rule, between 5 and 8 A.M. This paroxysm was at times alarming in its intensity, and would continue from one to three hours, but during the attack the heart's action would diminish after a fit of coughing, with the discharge of considerable quantities of bronchial mucus. The breathing would then get easier, but would remain somewhat embarrassed throughout the entire day, to be again exaggerated into a severe paroxysm the next morning. After the fifth day the patient had no paroxysms of dyspnea, and very soon thereafter commenced to be convalescent.

During March, April, and May, this patient had a number of asthmatic attacks of much less severity than the one described. Since that time (now almost a year) she has not had a single attack of dyspnea. I was very careful to assure myself that there was no heart or kidney lesion to account for the dyspnea. The urine passed during a severe asthmatic attack was acid, specific gravity 1024, no albumin, no casts, contained an excess of uric acid, and a large excess of paraxanthin and xanthin. From 1½ quarts of urine I separated both xanthin and paraxanthin. The paraxanthin solution separated from this urine was poisonous to mice, the mice dying with the characteristic symptoms of paraxanthin poisoning, one of which is severe *dyspnea*. One and one half quarts of urine passed by this patient in the interval between the attacks did not contain an appreciable quantity of paraxanthin.

Upon this evidence I conclude that paraxanthin was an important factor in producing the paroxysms of dyspnea from which this patient suffered. In this case, as in others that I have examined, I believe the symptoms were due to an overproduction rather than to a deficient elimination of paraxanthin. I emphasize this point, since it will appear later in this paper that I have reason to believe that the dyspnea (a uremic symptom) of acute and chronic Bright's disease is in part due to the deficient elimination of this same poisonous leukomain, which in very small quantities is one of the ingredients of normal

[1] Read before the Association of American Physicians, Washington, April 30, 1896.

urine. In this connection I wish also to express the opinion that the characteristic symptom in each of the four types of leukomain poisoning, which I have described, is produced by paraxanthin rather than by the less soluble and less poisonous leukomains associated with it in these diseases. That is to say, such symptoms as may be produced by xanthin and heteroxanthin are for the most part obscured by the paraxanthin poisoning. The characteristic headaches, the epileptoid convulsions, the gastralgia and the asthma may, therefore, very properly be called symptoms of paraxanthin poisoning.

From this phase of my subject I wish to pass to the study of the group of nervous symptoms so commonly associated with chronic alcoholism and chronic lead poisoning, since it is my belief that certain of the nervous symptoms, which occur in these conditions, are in part due to leukomain poisoning.

Chronic Alcoholism.—The importance of chronic alcoholism as a factor in the production of the gouty diathesis suggested to me the possibility that leukomain poisoning might be a factor in the production of the convulsive seizures which occur in chronic alcoholism, and also of the nervous symptoms which are grouped under the term "delirium tremens." Possessed with this idea, I attempted its solution by an examination of the urine of such patients. Some difficulty was experienced in obtaining suitable specimens of urine, as it had to be collected by catheterization, an operation which is at times attended with difficulty in these obstreporous and delerious patients. I did, however, succeed in getting three fairly representative specimens of delirium tremens urine, and from the examinations of these urines, I concluded that paraxanthin was a factor in producing the nervous symptoms from which chronic alcoholics so commonly suffer.

One of these cases, which occurred at the Cincinnati Hospital, in the service of Dr. George Fackler, is here given in detail. The urine was kindly collected by Dr. Shields, the resident physician.

No. 72,461, J. K., age thirty, teamster, an American, single, male, and of fair physique, was admitted to Cincinnati Hospital, November 18, 1895. Family history of phthisis, otherwise negative. He has hemorrhoids, denies venereal disease, but admits chronic alcoholism extending over a period of two years. He never had delirium tremens before, but recently he had been very nervous except when under the influence of liquor. He drank whiskey before breakfast to "settle his stomach and quiet his nerves." After a week of very hard drinking he was brought into the hospital suffering from delirium tremens. He was so unruly that it was necessary to strap him to the bed. In his delirium he was selling potatoes.

The physical examination, apart from the tremor, revealed nothing of importance, the urine was saved by catheterization. Patient was ordered bromid of potash grs. xxx, and hydrate of chloral grs. xx, every three hours, when awake. November 19th, slept some, is delirious when awake; 20th, slept all night, still delirious; 21st, slept well, no delirium; 25th, discharged well.

Examination of two quarts of urine excreted on November 18th and 19th, sp. gr. 1020, acid, yellow, no albumin. An excess of uric acid, and a small quantity of paraxanthin was found. The final fluid was evaporated to two cubic centimeters, and this fluid in large doses produced paraxanthin poisoning when injected into mice.

From a study of this and two other cases, I conclude that paraxanthin is present in excess in the urine passed by patients suffering from delirium tremens. In the light, therefore, of the known poisonous properties of paraxanthin, the inference seems fair that this leukomain is one of the factors which assist in producing the nervous symptoms of delirium tremens and the convulsive seizures of chronic alcoholics.

Lead Poisoning.—The fact that chronic lead poisoning may be the all important factor in the production of the gouty diathesis suggested the possibility that leukomain poisoning might be a factor in the production of lead encephalopathy and possibly others of the nervous symptoms of chronic lead poisoning. It is an interesting fact that the groups of nervous symptoms which may result from chronic lead poisoning and chronic alcoholism are very similar to the group of nervous symptoms which may occur in the gouty diathesis. The migraine, the epilepsy, the gastric neurosis, and the asthma, which are among the classical symptoms of so-called masked gout, and which I have demonstrated to be due to leukomain poisoning, have their analogues in the paroxysmal headaches, the epileptoid convulsions, the gastro-intestinal attacks, and the dyspnea, which not infrequently occur as symptoms of chronic lead poisoning and chronic alcoholism.

J. C. Wilson in his paper[1] on "Chronic Lead Poisoning," says "Naunyn has pointed out the resemblance between the nervous and psychical derangements in lead encephalopathy and those

[1] System of Medicine, Pepper, p. 1386.

which characterize chronic alcoholism, and suggests that lead, like alcohol, produces these effects, not as a direct poison, but indirectly in consequence of abnormal nutrition of the whole system, brought about by the continued circulation of a foreign poisonous material in the blood." It will presently be seen, in the light of my investigations, how strangely near the truth is this fortuitous suggestion of Naunyn, since my studies during the past year, the results of which I here present, have convinced me that the epileptoid convulsions, one of the most characteristic symptoms of lead encephalopathy, are due to the direct action on the nervous centers, of paraxanthin which exists in enormous excess in the urine of these cases. Only one case of well-marked lead encephalopathy occurred in the Cincinnati Hospital during the past year, and that case is here reported by the courtesy of Dr. Joseph Eichberg in whose service it occurred.

Case I.—A. S., German, 55 years old, of good physique, has been a lead worker for years, but has never had an attack of lead poisoning before. September 29, 1895, he was brought to the hospital in a semi-comatose condition which had followed an epileptiform convulsion. It was learned that he had been sick only two days, and that he had never had a convulsion prior to this one which caused him to be sent to the hospital. For some hours after entering the hospital he was slow to understand and answered questions in an incoherent way. His bowels were constipated, and his stomach irritable, temperature 97°, pulse 68, respirations 20. Patient has a blue line in the gums, a coarse tremor of the hands and a weakness of the extensor muscles of the forearms, tongue is coated but moist and shows marks of fresh laceration, evidently caused by the teeth in the convulsion previously mentioned. His abdomen is retracted, but he complains of no pain or tenderness in it. His heart, lungs, and spleen are normal.

Treatment.—Epsom salts ℥ i. every hour till bowels have moved freely. October 1. Slept well, temperature and pulse normal, mind has remained sluggish, bowels have been kept open with salts. October 2. At 6 P.M. he had an epileptoid convulsion; the muscular spasm was, in the beginning clonic, and afterward tonic.[1] He frothed at the mouth and lacerated his tongue during this convulsion which lasted three minutes. Violent delirium immediately followed the convulsion and continued till 8 P.M. He was given $\frac{1}{150}$ of a grain of hyosin, and 30 grains of bromid of potash. At 2 A.M. he went to sleep and slept till morning. The nurse was ordered to save the urine passed immediately following the convulsion. One quart in all was procured for examination. October 3; he is rational and calm this morning after his sleep, and answers questions fairly well. His bowels are constipated, his breath is foul, and there is slight tremor. He was given Epsom salts. October 6. Has been doing well, sleeps all night and complains of nothing except slight pain in bowels, probably from the salts, which have been given every day to keep the bowels open. Urinalysis: Urine yellow, sp. gr. 1020, acid, no albumin, no sugar, but lead reaction was well marked. (Previous to this time the urine had not been examined for lead). October 8, Patient feels well, sleeps good, has a fair appetite, there is a slight tremor present, and extensors of left hand are still weak. October 10. Patient doing well, ordered comp. tinct. of chinchona ℥ i. and tinct. nux vomica gtts. v. three times a day. October 20. Has not complained of anything during the past ten days, his bowels have been kept open, his appetite has been good, and he seems securely convalescent. During the past two days two and one half quarts of his urine were saved for examination, for the purpose of comparison with the urine passed just after the convulsion.

Examination of Urine.—Specimen No. 1. One quart of urine, passed after the convulsion of October 2d, contained lead and a large increase of uric acid, sp. gr. was 1024. It contained no albumin and no sugar, but the special purpose for which the urine was saved, was to determine the presence or absence in it of *xanthin* and *paraxanthin*. This urine was therefore examined for these bodies by the method set forth in my paper on "Leukomain Poisoning,"[1] and found to contain a trace of xanthin and a *considerable quantity of paraxanthin*. The great increase in the quantity of paraxanthin present in this urine can best be appreciated by remembering that nine liters of normal urine are necessary to demonstrate its presence (Salomon), while in this specimen, from one quart of pathological urine, paraxanthin was found in considerable quantities.[2]

Following the chemical tests I subjected the "final fluid" to the physiologic test for paraxan-

[1] I have arranged, but not otherwise changed these notes, which were taken by resident physician Dr. Robert Jones, who materially assisted me in obtaining the specimens of urine from this patient.

[1] "Transactions of Association of American Physicians," Vol. x, 1895, and *New York Medical Record*, June 22, 1895.

[2] The chemical tests which I use for determining the presence of xanthin and paraxanthin in the "final fluid" are as follows:

Xanthin I.—A drop or two of the suspected liquid and two drops of C. P. nitric acid are evaporated over an alcohol lamp, when xanthin is present a lemon-yellow residue is left. This is not changed by ammon. hydrate, but changes into a purple-red with potassium hydrate.

II.—A few drops of the suspected liquid are mixed with very little bleaching powder and sodium hydrate in a water glass. The solution becomes covered by a dark-green scum, which changes into brown and then disappears.

Paraxanthin I.—A few drops of a concentrated solution of potassium or sodium hydrate are added to a few drops of the suspected liquid; a white, glittering precipitate is formed if the suspected solution contained very much paraxanthin; if little paraxanthin is present the solution will be only cloudy, but will increase in cloudiness after standing awhile.

II.—A few drops of the suspected liquid are mixed with a little chlorine water, containing a trace of nitric acid and evaporated; when dry they are exposed to an ammoniacal atmosphere, if paraxanthin is present, a beautiful rose-red color is produced.

thin by injecting it into mice. In a very large number of examinations I have never failed to produce paraxanthin poisoning in the mouse, when the chemical examination showed that paraxanthin was present, and I have always failed to produce paraxanthin poisoning in the mouse with a "final fluid," in which the chemical examination said that there was no paraxanthin. For a detailed account of the symptoms of paraxanthin poisoning in the rat and mouse the reader is referred to a previous publication.[1] It will be sufficient here to say that the convulsion is one of the most striking and characteristic symptoms, and that in the beginning the convulsion is clonic and afterward becomes tonic or tetanic. It should here be noted, by reference to the note in the above history, made by the resident physician on October 2d, that the "epileptiform convulsion" which this patient had on that date, resembled a paraxanthin convulsion in the mouse; that is to say, it was "in the beginning clonic and afterward tonic." In the light of these facts the physiologic test of the "final fluid" from the urine of this patient assumes special importance. This test was made in the presence of Dr. F. Southgate and Mr. H. Wherry, who assisted me in making these observations. Three minims of the "final fluid" when injected into the back of a mouse, produced death in five minutes. The mouse died in convulsions, and the muscular movements were at first clonic and then tonic or tetanic.

There is yet one other important bit of evidence which must come in before one can pass judgment on the cause of the convulsion which this patient had on October 2d, and that is that in the specimen of urine (two and one half quarts) passed by this patient, during his convalescence, on October 19th and 20th, I failed to detect paraxanthin, and only a trace of xanthin was found. In my former papers I have noted the fact that an excess of paraxanthin in the urine means, that previous to its excretion, there was an excess of paraxanthin in the blood.

In view of all the facts above given it seems a rational conclusion that the convulsion which this patient had on October 2d was due to an excess of paraxanthin in his blood; this paraxanthin was excreted and found in excess in the urine passed immediately after the convulsion, and when separated from the urine produced the same kind of a convulsion in the mouse.

CASE II.—D. C., 35 years old, has been a lead worker for years and has had lead colic twice before. June 1, 1895: He was admitted to the Cincinnati Hospital suffering from lead poisoning. The blue line at margin of gums was well marked. Patient had a severe attack of lead colic which lasted twelve hours. Two quarts of urine, passed during and subsequent to the attack, were saved, and examined for xanthin and paraxanthin. June 5th. Man discharged well, he had only the one paroxysm of pain, and was convalescent the next day.

Examination of Urine.—Two quarts passed during and after an attack of lead colic contained *no paraxanthin* but contained *considerable xanthin.* The "final fluid" when injected into mice did not produce convulsions.

CASE III.—F. M., age 41, lead worker, was admitted to Cincinnati Hospital September 18th, and discharged September 21, 1895. During the three days he was in the hospital he suffered from lead colic, and was discharged "improved" at his own request. The attack of colic was not very severe, and was accompanied by arthralgia.

Examination of Urine.—Two quarts of urine failed to show the presence of paraxanthin, but xanthin was present in excess. The "final fluid" in small doses was not poisonous to mice.

In these urine examinations it will be noted that the patient who had "considerable" paraxanthin, had little xanthin in his urine, and that the patients who had "considerable" xanthin had no paraxanthin in their urine. This same observation was made in the examination of a number of urines of different kinds; very commonly when xanthin was found in excess, no paraxanthin was found, and it was also observed that the presence of paraxanthin in excess did not necessarily indicate an excess of xanthin. I may also remark in this connection that the presence of xanthin or paraxanthin in excess in the urine was not always associated with an excess of uric acid in the same urine.

Remarks on the Pathology of Lead Poisoning.—From the evidence given in this and in my previous papers, the conclusion I think is justified, that xanthin and paraxanthin plays an important rôle in the production of those nervous symptoms of chronic lead poisoning which can not be explained by degenerative changes in nerve tissue. Included in this group of functional symptoms may be mentioned amblyopia, headache, vertigo, neuralgia, colic, arthralgia, delirium, convulsions and temporary insanity. This group of nervous symptoms has never been satisfactorily explained by the pathological findings in chronic lead poisoning. Neither has any theory of this disease been comprehensive enough to furnish a rational explanation of these symptoms. One cannot understand how the direct action of lead on the

[1] MEDICAL NEWS, May 26, 1894.

nervous system can produce this group of symptoms, but one can understand how, in the perverted metabolism going on in degenerating muscles, nerves, and other tissues, not only uric acid, but also the closely allied uric acid leukamains, xanthin, paraxanthin, and heteroxanthin may be formed in such excess as to make them potent factors in the production of the above-named nervous symptoms. This theory founded, I think, for the most part on fact does not detract from the important rôle which the direct action of lead on tissues plays in the pathology of this disease. To the action of lead may be attributed the impaired nutrition and the degenerative changes in nerve and muscle tissue. In short, lead may be accused of producing all the morphological changes which are recognized as a part of the pathology of chronic lead poisoning, leaving to xanthin, paraxanthin, heteroxanthin and possibly other poisons of this class the production of the above-named nervous symptoms, which cannot be explained by structural changes.

In this connection it is impossible for me to resist the temptation of calling attention to the remarkable similarity which exists between the nervous symptoms of gout and the nervous symptoms of chronic lead poisoning, and of further noting the fact, that these two conditions have almost the same pathological anatomy. This may be taken as evidence that the one pathological factor—leukomain poisoning—which, as I have demonstrated, these two morbid conditions have in common, may possibly have something to do with the structural changes as well as with the nervous symptoms which occur in these two diseases. Concerning this question I shall have something to say in a later communication. I pass it for the present, that I may call your attention to another most important phase of autointoxication, viz.:

UREMIA.

In this, the closing paragraph of my paper, I shall not have time to discuss the broad subject of uremia. It is my purpose therefore, here merely to present a portion of the evidence which has convinced me that paraxanthin is a very important factor in producing the symptom conplex which we call uremia. In considering this subject, I would ask that the following statements be kept in mind.

1. Paraxanthin poisoning in the mouse is characterized by an increased reflex excitability which is followed by stupor, dyspnea, and convulsions. The convulsions are in the beginning clonic and then become tonic or tetanic.

2. In this and previous communications I have demonstrated that paraxanthin may be an important factor in producing the following symptoms, viz.: headache, gastric pain and gastric irritation, asthma and convulsions.

3. The most characteristic symptoms of uremia are headache, gastric irritation, dyspepsia, stupor, muscular twitchings and convulsions.

The above statements are here presented since their suggestiveness led me to inquire into the presence or absence of paraxanthin in the blood of uremic cases.

Case No. 66,104. Age 57, pedler, American, single, of good physique, was admitted to Cincinnati Hospital January 11, 1896, for soft chancre. He had syphilis nine years ago. At time of his admission to hospital he had diarrhea, a paroxysmal cough, edema of feet and a sore about the size of a dime on the under surface of prepuce. His urine contained albumin and casts. He remained in the surgical ward till February 21st when he was transferred to the medical ward service of Dr. J. C. Culbertson, because of well marked uremic symptoms, which had recently developed. At this time the edema was marked, the cough was paroxysmal, he was delirious and passed his urine involuntarily. His wild delirium gradually gave way to stupor, which on February 24th deepened into a semi-comatose condition. At this time 200 cc. of blood were removed from the patient's right arm, but no improvement followed this venisection. The uremic symptoms deepened and he died in uremic coma on February 25th.

Post-mortem examination, confirmed the diagnosis of death from uremia due to interstitial nephritis. Examination of the 100 cc. of blood which was obtained by venisection on February 24th, when the patient was in a semi-comatose condition, revealed the presence of paraxanthin, but not a trace of the other xanthin bodies. The paraxanthin solution obtained from the blood of this patient killed mice with the characteristic symptoms of paraxanthin poisoning.

I cannot be mistaken in the fact that paraxanthin was obtained from this blood. But there are other sources of error which must be investigated before paraxanthin can be justly accused of taking part in the production of the symptoms from which this patient suffered. In the first place we must inquire whether paraxanthin can be found in normal blood, when subjected to the same method by which paraxanthin is found in uremic blood. To answer this question, I examined 250 cc. of my own blood, which I obtained by venisection from my arm. In this blood I failed to find even a trace of the xanthin bodies. And I therefore concluded that paraxanthin did not exist in

appreciable quantities in normal blood, and that it was not developed in blood while being subjected to the process by which the xanthin bodies are isolated.

The second question to be inquired into, as a possible source of error, is, cannot paraxanthin be found in the blood of a patient dying from any disease? Or in other words, is it not possible that the paraxanthin may result from some abnormal body chemistry which shortly precedes death? In answer to this question, I examined the blood of a Cincinnati Hospital patient, No. 73,746, from the service of Dr. J. C. Mackenzie. This patient was admitted to the hospital on March 8, 1896, in a comatose condition. On March 10th, he was bled from the median veins in both arms. About 400 cc. of blood in all were taken. The patient died the next day, March 11th, and the *post-mortem* examination revealed the fact that he died from cerebral hemorrhage. In the 400 cc. of blood obtained from this patient, I failed to find paraxanthin. The type of unconsciousness in this case was very like that which occurred in the case of uremia above reported, but in one instance the coma was produced by uremia and in the other by cerebral hemorrhage.

In the light of these facts, therefore, I am of the opinion that paraxanthin is an important factor in producing that complexity of symptoms which we call uremia.

PULMONARY CONSUMPTION AS A FACTOR FOR THE ELIMINATION OF THE UNFIT.

By THOMAS J. MAYS, A.M., M.D.,
OF PHILADELPHIA;
PROFESSOR OF DISEASES OF THE CHEST IN THE PHILADELPHIA POLYCLINIC, AND PHYSICIAN TO THE RUSH HOSPITAL FOR CONSUMPTION IN PHILADELPHIA.

Pulmonary consumption is regarded by many as a scavenger whereby the weaklings and the unfit are removed, in order that the human race may be saved from decay and death; and all efforts at amelioration and cure are not only looked upon as a waste of time and money, but as a retardation of progress and civilization. This feeling has no doubt been fostered by the seemingly great and relentless fatality which has hitherto attended this disease. By some it is believed to be a dim memory which survives of a barbarous and half-civilized era, when it was considered necessary to abandon and to sacrifice the sick, the aged, and the infirm, for the sake of protecting the remainder of the social fabric. But whatever its source may be it is quite evident that this impression does not represent a very high degree of altruistic feeling, and that it is, in all probability, based on a misconception of the nature of the disease to which it relates.

This becomes quite manifest when we study the causes and conditions which originate this disease. From this we learn why so few families are exempt from its invasion, and why its victims, the number of which are nearly constant from one year to another, are selected with a certainty which is as startling as it is painful. Perhaps the most instructive lesson that can be drawn here is from the transmission of the tendency to this disease from parent to child. In estimating the potency of heredity we must take into account the fact that statisticians differ in their estimates, because they include various degrees of relationship. Thus when parental influence alone is considered the percentage is lower than if that of the whole family is embraced, and hence different authors make calculations which vary from thirty to seventy per cent. Moreover pulmonary consumption may be inherited from nervous diseases. Thus insanity, idiocy, hysteria, chorea, epilepsy, and asthma are translated into pulmonary disease between parents and children, and the latter is convertible into the former in the same way.

Here lies a most fertile source of pulmonary consumption, and one which has received very little attention from investigators. Dr. Blandford, a high authority on diseases of the mind, states[1] "I have found phthisis and insanity frequently coexisting in the same family." Dr. Stearns says:[2] "We often see a consumptive having a child which, instead of developing consumption develops insanity, and *vice versa*; insane parents may have children of a phthisical tendency." Dr. Mosher relates[3] the interesting history of a woman who suffered from lung disease and who had been insane for eight years, whose eight paternal great uncles and great aunts had died of phthisis, and whose paternal grandfather was epileptic. Dr. Clouston makes the observation[4] that the death rate from pulmonary consumption among the insane is four times higher than it is among the general population, that both diseases are very common in different members of the same family, and that heredity toward consumption may determine insanity, and that heredity toward the latter may produce the former disease. The same eminent authority makes the remark[5] that the form of insanity which is commonly associated with phthisis is monomania of suspicion

[1] "Insanity and Its Treatment," p. 56.
[2] *American Journal of Insanity*, 1888, p. 87.
[3] *New York Medical Record*, 1895, p. 390.
[4] "Neuroses of Development," p. 91.
[5] "Lectures on Mental Diseases," p. 461.

and melancholia; that nearly all pure cases of this kind sooner or later die from phthisis, and that the constitutional weakness which tends to end in insanity is akin to that which tends to end in phthisis.

There is a similar prevalence of consumption in families which are burdened with idiotic children. Thus it has been found that in one hundred families, taken at random from the general population, about eighteen members die from pulmonary consumption, but in one hundred families, each of which contain an idiotic or a hysterical child, the death-rate from this disease rises to nearly a hundred and fifty among its members—showing a mortality-rate about eight times greater than among the general population. Indeed the influence of heredity in transforming almost any nervous disease into pulmonary consumption, or the reverse is so obvious that it has not even escaped the eye of the lay writer. In the weird story of Dr. Pascal, Zola makes the latter acknowledge the fearful heredity which overhangs and threatens his life.

On the other hand, the poison of influenza and whooping-cough, alcohol, lead, mercury, etc., are powerful exciting causes of pulmonary consumption. Among lead-miners this disease is about three times more frequent than it is among the farming population of the same locality. The majority of those who are engaged in the manufacture of mercury, as mercury-miners, mirror-gilders, etc., die from pulmonary consumption. More than this, the offspring of those who suffer from mercury poisoning are exceedingly prone to suffer from this disease, as well as from rickets and scrofula. In fact, all evidence goes to show that any influence or agent which has the power of depressing or of disintegrating the brain and nervous system, as is the case with alcohol, lead, mercury, etc., also has the power of inciting pulmonary consumption and other forms of lung disease.

From what has been said so far, the impression may prevail that all consumptives belong to a degenerate class, and are hardly fit to survive the struggle for existence. The truth is, however, that the nature of very many of those who are in danger of dying from this disease, stamps them as individuals of the highest order of beauty and intelligence. They are excessively sensitive and nervous, and their intellectual and emotional faculties are often evolved to an extraordinary degree. Speaking of this peculiarity, Dr. Churchill says[1] that the connection between acute sensibility and phthisis is so striking that poets of all times and all countries have employed their most touching accents to deplore the premature fate of some of those victims to consumption whose youth was bright with promise of future excellence and distinction.

Where is the physician who has not seen a family of brilliant and beautiful boys and girls grow up one after the other, and to be then wiped out of existence at almost a single stroke from this deadly destroyer? How many parents are to-day lingering over the wasting and feverish frame of a dear son or daughter, whose cup of joy and happiness was running over, and whose life seemed to be radiating with every prospect of physical and spiritual greatness? Not only have poets sung of the beauty and grace of those who belong to the scrofulous or consumptive temperament, but men of science have been attracted by these characteristics, and have described them in the most felicitous language. For example, Professor Miller says:[1] "The complexion is fair, and frequently beautiful, as well as the features. The form, though delicate, is often graceful. The skin is thin, of fine texture, and subcutaneous blue veins are numerous, shining very delicately through the otherwise pearly-white integument. The pupils are usually spacious; and the eyeballs are not only large but prominent, and the eyelashes are long, and the sclerotic shows a lustrous whiteness."

It appears that high intelligence and physical beauty belong to a certain type of the phthisical temperament, and that in all probability both are the outcome of a refined nervous organization. A refined nervous system implies an unstable and a delicate constitution, not delicate in a morbid sense, but by reason of the exalted position which it has attained in the process of evolution, it is more sensitive to and more readily thrown out of balance by unfriendly influences with which it incidentally comes in contact. All persons who are endowed with such supersensitiveness of the nervous system are less fit to undergo the severe and exhaustive struggles, which are necessary to maintain life in the transitory stage of our still imperfect civilization, than those whose feelings and impressibilities are more obtuse. A transition, for example, from affluence to poverty, worry, grief, and physical and mental strain would simply mean disaster to many of the former class, and in many instances it would lead to the madhouse or to a phthisical grave; while a similar experience in the latter class would produce no more

[1] "Consumption and the Hypophosphites," p. 262.

[1] "Principles of Surgery," p. 55.

than a temporary superficial ruffle in their lives. The illustrious Laennec said[1] that among the causes of pulmonary consumption he knew of none more certain than grief or melancholy, above all, when prolonged.

It is well known, too, that phthisis is more liable to occur at one period of life than at another, and that in this respect it also runs a parallel course with insanity. More people die from phthisis and become insane between twenty and thirty years than during any other period in life. The cause for this is in all probability referable to the fact that at this point the brain and nervous system undergo a most varied and complex development. It is true that the weight and bulk of this organic structure matures during the first eighteen years of life, but its greatest and most intricate functional development takes place after this period. At this time man encounters a new experience in the way of living. He is forced to face problems of which he possesses very little knowledge, and on the solution of which depends his future comfort or misery. He is like an animal that is confronted by a new geological age to which it must adjust itself in order to prolong its existence. His new environment is, of course, not of the same character as that which surrounds the animal, but its power is just as real and as pressing. He is removed from paternal protection, and is left to struggle for himself. He becomes burdened with family cares and duties. He has to face a civilization with its education and inventions; its diverse manners and customs; its changeable institutions; its rankling politics; its innumerable arts and sciences; its multiplicity of industries and employments; its burning life-contests; its prejudices, jealousies, and disappointments; and its accompanying proneness to excesses and abuses of all sorts. The brunt of the battle principally falls on his brain and nervous system; and if these organs are sufficiently flexible to bring about and maintain a normal adjustment between himself and his new relation he will be successful, but, if from any acquired or inherited weakness or excessive delicacy, they prove inadequate he will go down in the struggle.

That many lives are lost in this process of attrition is attested by the statistics of consumption, insanity, and various other nervous diseases. And that those who are endowed with a highly developed nervous system are exceedingly liable to fall victims to the first-named disease, has already been shown; but the one problem of the most vital interest is whether this decimation is to continue indefinitely. Shall those who occupy a most exalted position in the evolutionary process be immolated forever on this altar? In answer to this it may be stated that the health reports of nearly all large cities of this country and of Europe show on the whole that the mortality from consumption is gradually diminishing. Not only is this the case since 1882, when the discovery of the tubercle bacillus led to the adoption of precautionary measures in many places, on account of the supposed contagiousness of this germ, but this has been true for at least seventy-five years in London; for seventy years in New York; for forty years in Boston; and for thirty years in Philadelphia. This reduction can be ascribed to nothing else than to a better mode of living. Better food, better clothing and shelter, better homes, better schools, better physical and mental training of the young, better streets, better drainage, less work for some and more for others, less poverty, less crime, elevation of the moral standard through Christian teaching, are the sanitary agencies which have brought about these changes, and which will eventually effect a harmonious relation between man and his environment.

Facts therefore fail to confirm the belief that pulmonary consumption is designed to purge society of the unfit; on the contrary, sufficient reason has been given to show that many of those who fall victims to this disease are drawn from a class of society which represents the most progressive type of human development. Evidence has also been submitted to show that general sanitation tends to eliminate this disease.

The future is therefore full of promising possibilities, but what of the present? Are those who are suffering from this disease doomed, and beyond the hope of restoration? Is medical science unable to hold out any prospect of immediate relief for them? If it is, then it is more impotent than nature herself, for the morgue and the *post-mortem* room furnish frequent proof of lung disease—old scars, the remnants of phthisis once active, but now gone—in the bodies of persons whose death was caused by accident, or by disease other than that of the pulmonary organs. Now if this much is done spontaneously and unassisted, art should do more. The art and science of medicine are doing more, as is amply attested by the records of hospitals specially devoted to the treatment of this disease, and by those of private practice.

CLINICAL MEMORANDUM.

SOME EXPERIENCES WITH THE BACTERIOLOGICAL DEPARTMENT OF THE PHILADELPHIA BOARD OF HEALTH.

By WILLIAM DUFFIELD ROBINSON, M.D.,
OF PHILADELPHIA.

THE following cases which have recently occurred in my practice illustrate some interesting and unexpected results of bacteriological examinations in cases of sore throat.

On December 7, I was called to see Mrs. G. M., wife of the paying teller of one of the banks of this city. She complained that she had taken cold, and for two or three days had felt chilly, with general bodily pains. She also said that she "had swallowed a piece of orange peel which had gotten behind her palate," that she was unable to dislodge it, and that it caused her distress. At the time of my visit the patient was in the dining-room, her little three-year-old girl being on her lap. I found the temperature to be 104⅕°, pulse 138, tongue coated, but on careful investigation could find no orange peel, nor other foreign substance in the locality indicated by the patient. There was, however, over both tonsils, and on the pharynx, quite an exudate, of whitish character, and not perceptibly elevated; it had not at all the appearance of "dirty chamois skin stuck on the parts," said to be characteristic of true diphtheria. The patient did not complain of soreness of the throat, and there were no nasal symptoms. A culture tube was procured, and specimens taken from the exudate were sent to the Bacteriological Department of the Board of Health. Treatment was then begun, consisting of tincture of chlorid of iron, and bichlorid of mercury, and sulphate of quinin, internally, and the throat was treated every two hours by being first cleaned with a hot gargle of weak salt water, then with a gargle of dilute peroxid of hydrogen, and by having trypsin freely blown on the affected parts after each treatment. The patient had been but little among outside people and knew of no exposure to diphtheritic poison. The case did not seem to present the characteristics of true diphtheria; but the husband and children were at once isolated pending the report of the bacteriological examination. This report, received the next day, stated that the culture contained Klebs-Löffler bacilli, and that the case was, therefore, one of true diphtheria. Cultures were then immediately made from the throats of the husband and of the three children, aged respectively three, seven, and nine years; and their strict isolation was continued. The report from these cases was that all the cultures, except from the youngest child, contained the Klebs-Löffler bacilli.

At this time each of these four persons was to all appearances, and by all tests that could be made as to pulse, temperature, condition of the throat, and general feeling, in perfect health. Nevertheless their isolation was still enforced in order to avoid contagion from the mother, they having been removed from the house as soon as the nature of her disease was ascertained. Detailed examination of each person was made each day and they all continued in apparently perfect health until the seventh day after the first culture of the exudate had been made, when the husband was taken with chill, followed by temperature 103⅘°, pulse 140, and rapidly developing exudate on pharynx, and right tonsil. The exudate had developed between the afternoon and my visit at 10 o'clock next morning, and practically covered one-half of the surface of the right tonsil and pharnyx. In the children the temperature and all the apparent conditions remained normal, and they were separated from their father by his returning to his home. Another culture was made from the father's throat and the Klebs-Löffler bacilli were again reported.

On the second day following, being the ninth day since the children had been separated from their mother, the boy, aged seven, and on the tenth day of their isolation, the girl, aged nine, almost identically reproduced the symptoms which had appeared in the father—chill, high temperature, throat exudate, with duplication of the report of Klebs-Löffler bacilli from the Bacteriological Department.

Briefly stating the treatment in these cases, I would say, that of Behring's antitoxin, No. 3—a full bottle was injected into the thigh of each patient. The activity of the disease was recognized about 10 A.M., and the injections were made about 3 P.M. of the same day. A marked improvement was manifested in each of these cases in twenty-four hours, the boy's throat having cleared, and the temperature in no case being higher than 99⅖°. At the end of forty-eight hours each of these patients was practically well, with normal temperature, and clean throat, simply showing a little redness, which passed away within the next twenty-four hours. The bacilli continued to be found for the next four or five days in the boy; for ten days in the girl, and for fifteen days after the disappearance of the exudate, in the father's case.

The three-year-old child, although much more exposed to the contagion of her mother's breath than any of the other members of the family, from having slept with her, remained perfectly well, was returned to her home after its disinfection, now more than three weeks ago, and has had no diseased symptoms, nor has bacteriological examination discovered any diphtheritic bacilli in her case. Repeated examinations of the throat of the nurse, who had charge of these cases, failed to show any trace of the bacilli, and she left the house in perfect health.

Any physician can readily appreciate how difficult it was to keep this gentleman away from his business while he was feeling in such perfect health during the week of incubation and the two weeks following his apparent recovery, while the baccilli continued to be found. Epecially was this the case because there were only about three days during the activity of the disease that he experienced even a slight indisposition. It is also manifest what a terrible source for the distribution of contagion he would have been in his position as paying teller, handing money to hundreds of persons daily, with fingers often moistened with saliva laden with disease-bearing germs.

These cases illustrate, from the positive side, the value of bacteriological examination in cases of sore throat, even where diphtheria may be not at all suspected, showing, as

they do, how this process can detect the presence of the disease even where there are no other indications of its existence, nor, indeed, of any ailment whatever.

The next case may be regarded as of a negative character, showing how the bacteriological examination contraindicated the presence of diphtheria in a case where all the symptoms and circumstances seemed to affirm its presence, and how the accuracy and trustworthiness of the bacteriological method were demonstrated by the results.

Mrs. G., the mother of two children, one aged fifteen months, and the other four years, called me in. I found a history of chill, temperature 104⅕°, pulse 136, glassy eyes, and every indication of toxemia. An examination of the pharnyx revealed an exudate similar to that described as characteritic of diphtheria. It was in color a dirty-looking, yellowish white, and appeared as if the spots had been pasted upon the pharnyx and tonsils, covering one-third of all the parts visible back of the soft palate by compression of the tongue. A week previous to the beginning of her illness the patient had attended the funeral of a child who had died of diphtheria, the diagnosis in that case having been confirmed by bacteriological examination. Subsequently to the child's death, two dolls which had belonged to her were sent to patient for the amusement of her children. One of these dolls was much soiled, and had been much handled by the dead child during her last illness. Patient had handled the dolls herself a good deal to amuse her children, and the history of the case, therefore, gave excellent reason for suspecting contagion. On the first day a culture was made from her throat, before any antiseptic remedies had been used, and was sent to the Bacteriological Department for examination. Feeling confident that all the symptoms and the history of the case proved it one of true diphtheria, I began active, local and constitutional treatment, withholding, however, the antitoxin until I should have received the report of the results of the bacteriological examination. In order to get this report as soon as possible, I had arranged with the examiner that it be sent me by special messenger immediately on completion of the examination. It was received about noon, and, to my surprise, it was to the effect that the examiner had been unable to find any Klebs-Loffler bacilli, and that the department, therefore, could not, from a bacteriological standpoint, pronounce the case one of true diphtheria. They, however, requested that another culture be made, and that the case be carefully isolated, pending a repetition of the examination. This second and a third closley consecutive examination still failed to show the presence of the characteritic bacilli; and no antitoxin was injected. The woman entirely recovered in a few days, and the children have remained free from the slightest illness now for more than four weeks since their mother's recovery.

The next case is of a different class, but is pertinent in this connection as showing the accuracy of the bacteriological method, and its value in sometimes revealing the existence of a disease whose presence there are no other grounds for suspecting.

G. B., male, aged thirty-four, by profession a vocal musician; never of very vigorous health, and with a history of having had pneumonia six years and two years ago; was, after two years of good health, taken with a chill, very high temperature, rapid breathing, and great pain in lower part of left lung, apparently pleuritic in character, extending in modified form over much of the lung. Within twenty-four hours he began to spit, after coughing, a clear, colorless, tenacious substance, roughly mixed with a substance like freshly clotted blood. There was some dulness over the affected side on light percussion, with harsh bronchial breathing. In a modified degree the same condition prevailed in the other lung. The case was diagnosed as probably one of pneumonia rapidly progressing, and a specimen of sputum was immediately sent to the Bateriological Department to confirm, if possible, this diagnosis by the detection of the pneumococci, the characteristic micro-organism of pneumonia. The report was that no pneumococci had been found in the sputum, but that many tubercle bacilli had been discovered. The examination was repeated, with the same results. As the young man had not been ill for two years, and there had been no evidence of reduced physical vigor previous to his acute attack, this report was indeed surprising, and especially so in view of the acute symptoms then present. It was but eight or ten days, however, before the correctness of the bacteriological diagnosis was proven by the unmistakable evidences of an unusually rapid form of miliary tuberculosis, from which the patient has sunk with remarkable rapidity. At the present writing (five weeks since the first bacteriological examination of his sputum) he is practically moribund, it seeming impossible that he can live beyond twenty-four to forty-eight hours. The evidences of the ravages of the tubercular process have been characteristic and very plain.

MEDICAL PROGRESS.

Vagitus Uterinus.—Flatau (*Centralblatt für Gynäkologie*, 1896, No. 11, p. 293) has reported a case of a quartipara, at the normal end of an uncomplicated pregnancy, in whom the onset of labor was marked by copious hemorrhage. Placenta prævia lateralis was diagnosticated and, in the hope that the head would descend and act as a tampon, the membranes were ruptured through the partially dilated os uteri. The anticipated result was not realized, and a tampon of iodoform gauze became necessary. The hemorrhage, however, persisted, and podalic version was performed. With the outer hand grasping the head, an attempt was made with two fingers introduced into the uterus to bring the feet together. In the performance of this act the umbilical cord was compressed and at once cries were heard. These were repeated when the cord was again compressed. Version was finally effected successfully, and the child at once extracted. The infant was asphyxiated, but was resuscitated by mechanical irritation of the precordium. The explanation offered for the phenomenon observed is, that air was introduced into the uterus with the hand, and that compression of the cord induced dyspnea, with the resulting cry on the part of the fetus.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to The Medical News will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: J. RIDDLE GOFFE, M.D.,

SATURDAY, MAY 16, 1896.

THE AMERICAN MEDICAL ASSOCIATION.

The recent meeting in Atlanta met the expectations of those who attended it as fully as could be reasonably expected, considering the location —in a Southern city—at this season of the year. The number in attendance, although not quite up to the average, was sufficient to afford an inspiring audience, not only in the general sessions, but also in the various sections.

The difficulties in handling the business details of so large a meeting were ably mastered by the president, Dr. Beverley Cole; indeed, it is rare that the presiding officer shows so much tact in preserving the good nature of antagonists, while deciding promptly and positively the many points in numerous delicate and sensitive questions that arise.

The autocratic way in which those in authority ignored the memorial exercises ordered, by vote of the Society at a previous meeting, in recognition of the centennial of Jenner and his great discovery was endured with great forbearance. At the same time, it was no less a mark of disrespect to the eminent men who had been invited to participate in these particular exercises. And the vigor with which the friends of the movement insisted on being heard enabled the Association to lead in the celebration of an event which will be the occasion of many celebrations in less conspicuous societies throughout the year.

In regard to the scientific work, the exercises were made memorable by the addresses of Osler, in general medicine, and Senn, in surgery. Both these men, while holding high the standard of scientific medicine, laid bare many shortcomings in its practice, and dealt rebuke with unstinted hand to those of the profession who abuse their privileges, either by neglect or by misdirected ambition.

The value of these meetings of the American Medical Association, in certain respects, cannot be overestimated. The objection, often advanced, that they afford opportunity for men, incompetent to speak with authority upon any subject, to air their views and consume valuable time may be answered by the cogent consideration that this is, likewise, just the opportunity to explode the false conceptions thus promulgated. The faddist who claims that typhoid fever can be aborted in five to seven days, and, in a vein of over-confidence, nonchalantly announces that "any physician who loses a case is criminally guilty of malpractice," suddenly finds that he has exploded a bomb, whose reactionary force is apt to set him thinking. And when a sober provincial, in a highly moral paper, advances the claim that small doses of alcohol, ranging from fifteen drops to two drams, dilate the capillaries and act as a heart depressant, is told that sentimental reasons cannot controvert carefully observed physiological facts, he, as well as others like him, is apt to go home a wiser though perhaps a sadder man.

The social functions attendant upon the meeting fully realized the hospitable greetings of the welcoming addresses. All the details of the barbecue were carried out with so much system that it lacked entirely the tiresome features so often a part of such a performance. The lovely day, the delightful grove, the attractive tables, reaching out their long length in the shade of the spreading trees, all combined to make a picture that will not soon be forgotten by him who had the pleasure of enjoying it.

RECENT ADVANCE IN GYNECOLOGY.

THE TREATMENT OF PUS IN THE FEMALE PELVIS.

Even a comparatively short experience in the practice of medicine will have sufficed to enable one to see great changes in the treatment of suppurative pelvic diseases of women. The opinions of learned and careful men have undergone almost revolutionary changes within the past five years, due more especially to improved methods of sterilization, and more careful anatomical study. Procedures which, a few years ago, seemed beyond hope of successful application are now commonly employed. Greater precision in the classification and analysis of cases has made it possible to formulate definite rules of action, and from the careful assignment of each case to its proper class sounder generalizations have been reached.

We may safely divide all cases of pelvic suppuration into two great groups: (*a*) Abscess of the ovary or of the tube, where the pus remains, contained within the walls of the diseased viscus; and (*b*) cases of diffuse pelvic suppuration, in which the pus has escaped from its original seat and has forced its way between coils of intestine and plates of lymph effusion. In this latter class must be included true broad ligament phlegmon.

The treatment of unilateral disease, including ovarian abscess and pyosalpinx, seems a simple problem. But here we find opinion diametrically opposed. Most American surgeons prefer the clean, straight abdominal incision, the removal of the diseased adnexa and closure of the abdomen without drainage. But in certain quarters the vaginal route is given precedence, some preferring to make the incision anterior to the cervix uteri and others giving preference to the incision into Douglas' pouch. It would seem that the traumatism attendant upon the anterior incision is greater than that incident to an abdominal section and is devoid of the attractiveness which attaches to open work where every step is seen. Of the abdominal route it may be said that every phase and variation is well known through long experience; that every possible complication has been met and the method of dealing with it is known, and, above all, that the probablity of entering a hollow viscus is so slight that it may be omitted from our calculations. Although we can fairly well cleanse the vagina by means of preliminary antiseptic tampons, curettage, and brushes, still must this cavity be classed among the hollow viscera, an entrance into which is undesirable.

Furthermore, all who have attempted vaginal section for unilateral disease must admit that the traumatism of the genitalia is less with celiotomy, that a more elaborate differentiation of conservative work can be applied through the abdomen and that the mortality from celiotomy in this class of cases is practically *nil*. To-day, at least, those who seek removal of *unilateral* purulent adnexa through the vagina are not supported either by experience or force of argument. The weight of both are with him who does celiotomy.

The treatment of *bilateral* suppurative disease also finds advocates for both the suprapubic and vaginal routes, furthermore we are all confronted here with the question of the advisability of removing the uterus. If the surgeon be one who leaves the uterus after he removes both adnexa, he will elect the abdominal route undoubtedly. But if he belongs to the camp of those who always remove the uterus when both adnexa are taken away for pus, and who never remove the adnexa unless the seat of purulent degeneration. he has presented to him two lines of precedure, the result of which immediately are the same and remotely identical. The abdominal route leaves a scar as an ever-present reminder of a grave operation, and there is a breach in the abdominal parieties with a remote chance of subsequent hernia through it. These are absolutely the only objections to the abdominal route.

There is little risk of wounding the bladder or bowels in the operation, and what damage is done to either can be easily repaired. The ligation of the vessels can be made either *en masse* or in continuity, and there is no secondary hemorrhage to be feared. The vaginal route is much the more difficult. Accidents of the hollow viscera occur in a too considerable percentage of cases; ligation of vessels in continuity is never possible; ligation *en masse* seldom practicable. The arteries are better secured by means of forceps, which produce nasty sloughs. There is no disagreeable abdominal scar, there is no possibility of ventral hernia; the discomfort immediately after the operation is about the same as after laparo-

tomy; but undoubtedly the general shock is less. How is the surgeon to decide between these two nearly equally attractive methods? Nowadays the patient will often demand vaginal operation. This is especially true in our large cities, where some operators take their patients into their confidence as to the beauty of the vaginal method and the disadvantages of the other. There are fashions in surgery as well as in dress. But a careful consideration of the possibilities of each procedure, its ultimate results, the accidents attending it, will lead the man who is unhampered by extraneous matters to elect the abdomen rather than the vagina as the place of his incision. In considering this statement the reader must bear in mind that reference is made to the class of cases which are designated as bilateral, but in which the pus has not escaped from the wall of the affected viscera. When we come to consider those complicated cases of *diffuse* pelvic suppuration all hope of local conservatism is abandoned and that broader conservatism alone is to be considered which seeks the preservation of the general economy.

When such a condition is approached from below, very often the uterus only can be removed, the ovaries and tubes being so firmly attached and so high up as to be beyond the reach of the operator for removal. The vaginal operation is then surgically incomplete, although the pus foci can be opened widely and a large pelvic Mickulicz tampon employed. Even though such an incomplete operation be done, it is an open question whether the results, both immediate and ultimate, are not better than those resulting from a complete abdominal section which necessitates the use of Mickulicz tampons. In America at least, very often a suppurating appendicitis is associated with pus tubes and not infrequently there are fistulous openings into the intestine above the pelvic brim. These cases are to be considered as demanding celiotomy rather than vaginal section; for the intestinal lesion is of paramount importance and requires a careful manipulation. By vaginal section, in some cases, such a condition can be discovered but in very many it cannot. It is to be found in all cases where the pus foci on the right side are attached at the pelvic brim.

But there is another side to this question of the treatment of pus in the pelvis; the woman's side. No man who has watched his cases can deny that most unfortunate is the woman whose menses have been stopped before she is thirty years old. Too often is her neurasthenia and melancholia painfully in evidence. The greater her intelligence and refinement, the more active her mind, the more distressed is she. The women of lower cast, who have hard manual labor to perform, suffer mentally less. So that, in certain cases, especially in young women, many surgeons content themselves with widely opening the cul-de-sac, emptying the pus sacs and packing them with iodoform gauze. This procedure must not be confounded with the blind vaginal puncture. The object sought is the obliteration of the pus sacs, but the preservation to the woman of her menstrual functions free from genital atrophy and the distress of a premature menopause. So deeply averse are some surgeons, men fully capable to do any required work, to the mutilation of women that they always lay before those afflicted in this way the possibilities of the cul-de-sac drain.

This whole subject may be summarized in this way: In diffuse pelvic suppuration, hysterectomy, is always indicated, because drainage behind the uterus will be insufficient. In simple bilateral tubo-ovarian suppuration, the cul-de-sac incision and a large pelvic Mikulicz tamponade of iodoform gauze into the opened pus sacs, will symptomatically cure the vast majority of cases. If it fails to cure, relief is temporarily afforded and a radical operation can be done at the *elective time*. The possibility of the latter is the glory of the vaginal section. Surgeons are to consider whether it is not their imperative duty to first apply this procedure, which so often cures and which always benefits; which carries with it no accidents, and which preserves to the woman her menstrual functions.

William R. Pryor, M.D.

ECHOES AND NEWS.

The New York Orthopedic Dispensary and Hospital has recently received gifts amounting to more than $50,000.

Dr. Charles A. L. Reed of Cincinnati, has been selected by the European committee on organization of the International Periodical Congress of Gynecology an

Obstetrics, as honorary president of the meeting of that body, to be held in the city of Geneva, Switzerland, the first week in September of this year.

THE ILLINOIS STATE BOARD OF HEALTH have decided to recognize the diplomas from no medical college that does not exact a four years' course. Thus all of her colleges have been forced to adopt this plan, but it should be stated to their credit that many of them had adopted this rule in advance of the present demands from the State authorities. The reciprocal recognition of medical diplomas already exists between Illinois and several foreign countries.

IN an elaborate study of statistics furnished by the London primary schools relative to their influence in the spread of diphtheria Dr. Smith concludes that this danger has been greatly overestimated. He regards the relations existing in them as far less important in its propagation than the habit of kissing among girls and the crowding together of children in their homes.

THE Brooklyn Centennial Festival in honor of Jenner, to be held on the 14th inst., will be attended by the following distinguished medical guests: Drs. William Pepper, of the University of Pennsylvania and William H. Welch of the Johns Hopkins; also by the Right Rev. Bishop Potter and Hon. St. Clair McKelway, Regent of the University and editor of the *Brooklyn Eagle*. A bronze metal has been prepared for presentation to each of the guests.

THE trustees of the Jefferson Hospital, Philadelphia, at their meeting on the 7th instant, accepted the resignation of Professor James F. Wilson as medical director, with great regret. Professor Wilson will still remain a member of the board. Dr. Joseph S. Neff was elected to fill the vacancy, and Charles Hebard of Chestnut Hill, was elected to the Board of Trustees.

LAST week five children were reported to have been born to a Kentucky couple at a single confinement and this week the enterprise of a woman of Fowler, Ind. who gave birth to six living children at one confinement requires notice.

IN the death of Baron Hirsch many charitable institutions in Europe have lost a liberal benefactor. It is stated that London charities especially will suffer, for to them he was a most munificent patron. In 1893 they were indebted to him for not less than £40,000.

THE arch anti-vaccination agitator at Gloucester, England has finally caused himself to be vaccinated, for the public good but against his convictions, he rather lamely explains.

THE *Sanitary Record*, April 24th, reports that at Neath, South Wales, two brothers named Edwards have died by variola. Their father had the disease about five weeks ago. Both the brothers were, three weeks ago, proffered vaccination but they refused. Each of them said that he would rather die than submit to the operation. The wife of one of the brothers was recently confined, and both she and her infant have taken the disease and have been removed to the hospital.

THE German Parliament on March 12th discussed a motion brought forward by Herr Foerster, a Socialist-Democrat, for the abolition of compulsory vaccination. Dr. Von Boettischer, Secretary of State, said that the Federal Council had by an overwhelming majority expressed itself in favor of maintaining the present law. The motion of Herr Foerster was then promptly negatived and compulsory vaccination is still the rule of the realm.

IN the *British Medical Journal* of February 8th, Dr. George R. Murray, who first instituted the treatment of myxedema by thyroid feeding, gives a further report of his first case. The patient was a woman, aged forty-six, who had had myxedema for four or five years. Treatment was begun in 1891, and has been continued ever since. The patient is still perfectly well.

THE Paris correspondent of the *British Medical Journal* writes that it has been proposed in the Chamber of Deputies that from the unreclaimed sums of savings banks and other deposit sums to the amount of £10,000 should be paid to the different French laboratories: £2600 to the Pasteur Institute and to the laboratories of higher education in Paris, including the Val-de-Grâce Hospital laboratory and the Alfort School of Veterinary Medicine, for the purpose of aiding researches on contagious diseases, especially those in connection with serums and vaccines; £5000 to the medical school laboratories of Lyons, Bordeaux, Montpellier, Toulouse, Lille, and Nancy, likewise to the veterinary schools of Lyons and Toulouse; also for the purposes of experimental research for contagious maladies, including the further study of serums and vaccines; and £2400 to the therapeutical, pharmacological, and medical chemistry laboratories of the medical faculties and pharmaceutical schools to be devoted to the study of the methods of treating contagious diseases, likewise of the drugs. Every year reports of the work done at these establishment, are to be sent to the Minister of Public Instruction. The minister will afterward send them either to the Academy of Sciences or Academy of Medicine.

A PROMINENT New York neurologist was recently under the fire of a cross-examination in a case where the plea of insanity was urged. This witness testified that the accused was not insane, and would not admit that the hereditary taint of insanity in a family would predispose a person to such attacks. The following were some of the thrusts and parries:

Q. Is not hereditary insanity a common cause of attacks among people?

A. It is not so much believed now as it was. The opinions have been modified.

Q. You say that in your book, from which I am reading?

A. That doesn't change my mind.

Q. Then doctors change their mind?

A. The same as lawyers,

Q. Is your book an authority?

A. That's for you to say.
Q. Well, what do you say?
A. Well, I have my doubts.

One of the New York dailies pertinently observes that "At present the signs forbidding smoking on the elevated railroad platforms serve no good purpose whatever. If only they were roughened with a coating of sand they would be useful for smokers to strike matches on." To which we would add that the printed legends issued by the New York Board of Health, relating to expectoration upon the cars and other public places are apparently held in thorough contempt by both the corporations and the public. A law uninforced is better rescinded, and unless these signs can be made to command more respect from people persistently indecent, as well as ignorant, they should be removed without delay.

There is said to be trouble in the Woman's Medical College of Philadelphia. The students recently made a formal complaint of the lack of clinical advantages which they had been led to expect, and the entire staff of internes, with Dr. Anna M. Fullerton, physician-in-charge, have tendered their resignations.

Dr. Judson Daland of Philadelphia, has been appointed professor of diseases of the chest at the Philadelphia Polyclinic Hospital.

Grave fears are said to be entertained by the sanitary authorities of both Cairo and Alexandria of an epidemic of cholera in Egypt in the near future. In the former place all efforts made to stamp out the disease during the past winter have been ineffectual. Nineteen new cases and twenty deaths were reported in one day in Alexandria and it is feared that the canal from which her water supply is drawn has been polluted. The natives conceal the cases whenever possible.

The battle at Krügersdorp between the Boers and Dr. Jameson's troopers has revived the discussion of gunshot wounds from modern rifles. More than forty patients, all of them suffering from bullet wounds, were received in hospitals after the engagement, and the *British Medical Journal* has received a detailed report of the nature of the injuries and after-effects. It seems that the wounds made by the Lee-Metford rifle were cleaner and healed more quickly than those produced by other weapons. Many of the shots, through fleshy parts only, healed almost by first intention. One burgher, shot through the lungs, left the hospital a few days after admission convalescent. The entrance orifice of the bullet was exceedingly small, and few of the larger vessels having been divided, the hemorrhage was, in consequence, slight, the wound closed almost immediately on itself. The exit was about the size of the entrance, and in all cases was much smaller than that made by the Martini rifle. Where the Lee-Metford bullets struck bone this was completely shattered. The flesh wounds inflicted by the Martini rifle were of a much more serious nature—namely, larger, jagged, slow in healing, with bad apertures of entrance and worse of exit. The majority of Jameson's men had limb wounds. Among the more severely wounded burghers there was one man shot through the head who lived ten days afterward, one shot through the abdomen, one through the lung, one through hand and lung, and one through the back. The general consensus of opinion among those who saw the effects of fighting in South Africa is that the Lee-Metford rifle or carbine is inferior to the Martini as a "man-slaying" weapon. It does not appear to have in many cases the power which it should possess of putting a man *hors de combat*.

The *Philadelphia Press* has information that the literary exploits of Dr. A. J. C. Skene of Brooklyn, are presently to be tried in the field of fiction. With every minute of his time exactingly filled, it is said he is still to find more time—his own, or somebody's else—to create a story having psychological problems in it, like Dr. Holmes' Elsie Venner, or like Dr. Weir Mitchell's latest.

The rational and encouraging vien in which Dr. Philip C. Knapp of Boston, in the current number of the *Century* treats the question "Are Nervous Diseases Increasing?" goes far toward mitigating the offense of presenting medical subjects in popular magazines. In this article it is asserted with all the authority that can be drawn from as yet incomplete statistics, that the increase in the relative number of insane among the more highly civilized nations is more apparent than real. This is owing to a number of reasons, the chief of which are the change of view entertained toward insanity and its treatment by society, who now look upon it as a disease and not a disgrace; and the present facilities for its better and more frequent detection. Dr. Knapp also shows that, although Americans are more restless—or rather more active—than other nations, they are not more prone to nervous maladies. The so-called American disease, neurasthenia, constituted only ten or eleven per cent. of all nervous cases presented at the clinics of several American charities, whereas, in Paris twelve per cent. are so classified. Moreover, a large number of the cases treated in America are among our imported population. In the matter of hysteria, its percentage in Europe is several times greater than obtains in America. The relation of nervous disorders to, and their dependence upon other physical defects, either inherited or accidentally acquired, is duly emphasized, after which it is proven that, as a race, we compare favorably in almost every particular with any other, and are hence not more liable to nervous disease, a fact which is borne out by the mortality tables of life insurance companies, as well as other sources of reliable information. The increasing vigor and self-reliance of our women has banished much of the semi-affected nervous vagaries of the past and replaced them by an admirable power of resistance and self-control. With a better understanding of their causes and a daily improvement in scientific methods for their prevention and control, it is concluded that nervous diseases are not increasing, but on the contrary, the natural inference may be drawn that they should be expected to diminish.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Forty-seventh Annual Meeting, held in Atlanta, Ga., May 5, 6, 7, and 8, 1896.

(Continued.)

Second Day—May 6th.

Section on Surgery and Anatomy.

Dr. H. H. Beach, Boston, Mass., presented the first paper upon

EXPLORATION AND TREATMENT OF FISSURES FROM SKULL FRACTURES.

The author claimed that fatal results which attend fracture of the skull when not due to the immediate destructive violence of the injury may be attributed to septic infection by the extension of the fracture into the oral or nasal cavities.

As possibilities of infection cannot be estimated before the development of unfavorable symptoms, when too late to institute antiseptic measures, however radical, conservative treatment should include at the first inspection of the wound, a most rigid asepsis, the exploration of fissures with the *utmost* precision, uncovering the whole circumference of the perforation in the skull for that purpose and providing unlimited drainage by widening the fissure into loosely connected bone that extends in the direction of the base. Since nearly fifty per cent. of brain abscesses originate in suppurative ear diseases, the isolation of this region from the brain and its attachments during the repairs of a fractured skull demands the serious consideration of the surgeon. It also suggests the question of a more radical clearing and asepsis of the ear cavities than can be obtained without anesthesia in cases where the temperature steadily rises, notwithstanding our precautions. The danger associated with such a plan lies in the possibility of forcing, by washing under pressure, septic material through a wide fissure into the skull-cavity, and emphasizes the importance of a competent primary asepsis of the ears in all fractures connected with them.

Cases were added illustrating the practice advocated.

Dr. J. C. Oliver of Cincinnati, presented

A REPORT OF FOUR CASES REPRESENTING INJURIES AND OPERATIONS UPON THE BRAIN.

Case I.—That of a man aged fifty-nine, who fell through a dust chute, striking upon his head. He presented ptosis on the left side, hemorrhage from the left nostril, motor aphasia, and the pupils were midway between contraction and dilatation, and did not react to light. There was no paralysis of the limbs, nor of the face. The autopsy showed that the symptoms were each dependent upon separate lesions. There was found rupture of the middle meningeal artery on the left side, a fracture of the left orbital plate, and also a distinct, separate fracture of the cribiform plate on the left side.

Case II.—A patient presenting Jacksonian epilepsy, the convulsion always beginning in the left leg then involving the left arm, the left side of the face, and then becoming general. Following the convulsion the patient would have left-sided paresis which would only remain for a few hours. After the attack he would become maniacal, in which condition he was dangerous to those about him. The convulsions in this case occurred in groups so that he would have ten or fifteen a day. Because of the symptoms, trephining was done over the leg center on the right side of the brain. A varicose vein in the diploe was found to have ulcerated through the internal and external plates of the skull and had also caused absorption of the dura mater at one point. At this point there was a small hernia or protrusion of the pia and brain. No other lesion was discovered. The course of the vein was bitten out with rongeur forceps and the channel in the diploe plugged with a sterilized match. Following the operation the patient was free from epilepsy for six months. After this he began to experience pain in his left leg and there was a gradual return of the convulsions. Believing that the return of the convulsions was dependent upon the adhesions which had formed, the patient was again operated upon nine months after the first operation and a plate of gold foil inserted in the deficiency in the skull. A few months subsequently, the patient died suddenly in the night from causes unknown. Subsequent to the operation he experienced no convulsions. An examination of the head after death showed no gross lesion of the brain. The gold plate had very effectually accomplished the purpose for which it was inserted.

Case III.—The patient in this case had an inflammatory condition in the left upper eyelid which went on to suppuration. This was opened and the patient returned to his occupation, that of a machinist. After being at work for about three weeks, he began suffering with pain in the head which was most marked over the left frontal region. He became stupid. On testing the vision it was found to be 20–70 in each eye. A choked disk was present in the left fundus. A paresis involving the right side was found to exist. The deep reflexes were normal. Temperature was slightly subnormal, the pulse was irregular and hard. The diagnosis of cerebral abscess of the left frontal lobe was made, and a trephining over this area and exploration of the brain in this region led to the evacuation of an abscess containing three ounces of pus. The patient recovered and is now in his usual condition of mind and body.

Case IV.—In July, 1895, the patient was treated for an acute otitis media. This condition persisted in spite of treatment. On the 13th of October the patient was found comatose, pulse about 90, pupils contracted, slightly reacting to light, Cheyne-Stokes respiration. This condition continued until the following morning, when he was removed to the Cincinnati Hospital. That evening his temperature was 103, he was delerious, pulse was rapid, he had divergent strabismus, no evident facial paralysis, pulse 132, respirations 26. He became very restless and had to be restrained. The reflexes were present and active; slight trismus was noticed. In view of the fact that these symptoms followed the ear trouble, and also in view of the very evident meningitis, it was deemed advisable to trephine over the temporo-sphenoidal lobe for pos-

sible abscess. This was done with a negative result. The left lobe of the cerebellum was then opened with likewise a negative result. The patient died within an hour after the operation. *Post-mortem* showed diffuse purulent meningitis involving both the base and the convexity. There was no localized accumulation of pus. The infection in this case followed along the carotid canal.

Dr. Ransohoff of Cincinnati, in discussing Dr. Oliver's paper, said: I would simply like to refer to the question of hemorrhage in these operations, and to mention a method which I have employed to overcome it. I introduce, about an inch from the surface of the tumor, a continuous chain suture, which I draw tight around the entire line of the incision. This can be done very rapidly, and the entire area of the skull is thus made absolutely bloodless. I make my incision within the line of the chain, and have never found that the introduction of this suture interfered in the least with the vitality of the flap.

CHOLELITHIASIS AND CHOLELITHOTOMY,

by Dr. Chas. H. Dunn, Minneapolis.

This paper was based upon a study of forty cases of gall-stone disease and a review of the chief literature upon the subject. In the author's opinion the indication for the operation of cholelithotomy were relative and imperative. If the attacks of biliary colic be frequent, the calculi not passed and the symptoms not relieved by a reasonable hygienic and medical course of a few weeks duration so safe an operation as cholecystotomy is doubly preferable to further delay, even though no very threatening symptoms have developed, first, as the cheapest escape from present suffering, and second, as a preventive measure against the ever possible dangers of cholangioitis, duct impactions, etc., which may entail a much more dangerous and trying operation upon the patient. With few exceptions, early surgical interference will eventually be considered a proper treatment of cholelithiasis. A very pertinent question is whether or not operation should be advised in the midst of a recent attack of colic, and Kehr, having, as he believes, learned to distinguish between gall-bladder colic and gall-duct colic, advises waiting when the latter exists, lest the stone be felt in the ductus or a difficult choledochtotomy need to be performed. Many will be quite unable to make this differentiation with any certainty, while to delay long with a calculus in this most dangerous locality will often jeopardize the patient.

The diagnosis once positively made, it would appear less difficult for a surgeon to approximate reasonably the burdens and the dangers of the disease in a given case, and to distinguish between when to advise waiting, when to recommend operation and when to insist upon it, than to formulate rules for others. Although one prominent authority regards the size of the stone as having an important bearing upon operative indications, as, in the first place, we can foretell absolutely nothing as to the size of the stones before they are removed or passed, and in the second place, however much the theory may appeal to rational simplicity, cases have occurred which prove that the facts fail to follow mathematical fancy. Ninety-five times out of a hundred, gall-stones occupy the gall-bladder alone or it and the cystic duct alone, and therefore, in the vast majority of cases, the indication appears to be to open the gall-bladder, remove the stones and *débris* and temporarily drain the diseased organ. In the author's opinion cholecystotomy with temporary fistula is the operation of election in the average case of cholelithiasis. Choledochtotomy is always difficult, frequently dangerous, and sometimes impossible of practical execution.

Dr. Donald MacLean agreed with Dr. Dunn and stated that a successful operation on the gall-bladder give gratifying results and left nothing to regret.

Dr. Alex. Hugh Ferguson of Chicago, considered that the most important question was when to operate, and in his opinion, when you find the gall-bladder enlarged so that apparently there is a tumor there, an operation should be performed. The size of the gall-bladder is no indication, and cases of one stone are more difficult than those of several stones. One should never wait until the development of pyrexia before opening the gall-bladder, although, as jaundice cases stand operations and chloroform very badly, as little operating as possible should be done in these cases. Of the two ways of getting at the common duct, the one internal and the other external to the duodenum, the internal is the better, and an oblique incision is usually preferable to the transverse as it gives more room.

Dr. Hunter McGuire of Richmond, gave it as his opinion that operations in these cases would some day be dispensed with as a method would be found to dissolve the gall-stones.

Dr. Dunn, in replying to the inquiry of Dr. J. C. Oliver of Cincinnati, stated that the case referred to in his paper of a patient who had died after having had two attacks of biliary colic without jaundice, had died of exhaustion. He considered the idea much too prevalent that in these cases there should be jaundice, or tumors, or colic resembling the pains of childbirth, as in none of his cases had he found tumefaction.

A FEW RECENT CASES BEARING UPON THE QUESTION OF OPERATIVE INTERFERENCE IN ABDOMINAL AILMENTS,

by Donald MacLean, M.D., LL.D. of Detroit.

The author referred to the great difficulty of deciding whether or not to interfere in cases of abdominal ailments, traumatic or otherwise, and mentioned a few cases in point. The first case mentioned was that of a woman, who had suffered from an absolute obstruction of the bowels for ten days, in which case, upon operation, a large egg-shaped calculus was found. The patient died within twelve hours. The second case was that of a man who, although he gave the history of several well-marked attacks of appendicitis, complained only of a feeling of weakness in the right iliac region at the time of the consultation. Operation was advised, the appendix was found distended with pus, and extensive intestinal adhesions were encountered. Patient made complete recovery. The third case was a young man who had had repeated attacks of appendicitis, and whose appendix, upon operation, was found deeply imbedded in an immense inflammatory mass which surrounded the cecum. The

fourth case was that of a man who was taken suddenly and violently ill with all the signs of appendicitis and suffered great distress from constant coughs, with excessive expectoration of an indescribably fetid character. Incision was made between the sixth and seventh ribs, on the right side, which fortunately tapped the depot of fetid pus, and the patient made an excellent recovery. The fifth case was that of a young man who was taken seriously ill some hours after he had been thrown from his bicycle. An operation was performed, and upon opening the abdomen the following condition was found. An ancient ulcer of the stomach had induced a firm adhesion between the pyloric end of the stomach and the duodenal mesentery. The jar of the fall had had the effect of separating this adhesion and thereby caused a rupture of the stomach at the point of the ancient ulcer and consequent adhesion. In spite of everything that could be done, the patient died twenty hours after the operation. A peculiar congenital condition was found in addition to the morbid process, namely, the left kidney was found situated just below the promontory of the sacrum, and was very small and very imperfectly developed. Complete suppression of urine existed from the time of the accident to the end of the patient's life.

Dr. Thomas H. Manley of New York mentioned a case of a young man who had been kicked by a horse, and who, when seen by his family physician, was in a state of profound shock, perfectly rational, but cold. Peritoneal hemorrhage was diagnosed, after a thorough examination, in spite of the fact that one would expect to have had a renal hemorrhage. Bad symptoms setting in on the fourth day, operation was recommended, and a horseshoe kidney was found lying over the cecum. About five feet from the duodenum were two large gangrenous patches, one of which had perforated. The patient sank and died. The question of the greatest importance is, What good would it have done to have performed a laparotomy immediately after the accident?

The President asked if Dr. MacLean considered that either of his patients died from hemorrhage, as he had removed a stone some months ago, and the patient died of hemorrhage on the third day.

Dr. J. T. Thomas, Pennsylvania, referred to the subject of enteroliths, and spoke of a case upon which he operated two years ago, and found an enterolith which entirely occluded the lumen of the intestine. The patient died in about two hours.

Dr. Winslow of Baltimore, stated that on opening the abdomen of a lady who had presented for three days symptoms of obstruction of the bowels, and in whom vomiting and persistent constipation were present, he had found complete intestinal obstruction, which had been caused by a gall-stone. The patient died shortly after the operation. He mentioned another case, that of a man who presented no other symptom than considerable pain in the abdomen and some vomiting, except the history of an injury caused by the pressure of a car. On operation, a genuine hernia in a sac, which was entirely within the peritoneal cavity, was discovered. This case also died.

Dr. Philip Marvel of Atlantic City, spoke of a case of a lady who had fallen suddenly in a store and who at half hourly intervals experienced hysterical convulsions for a number of hours. Total suppression of urine existed and at the autopsy but one kidney was found which was in the normal position on the right side and was not diseasrd.

Dr. McRae of Atlanta, mentioned a case of extreme rarity and one of important medico-legal interest. The patient had received a stab-wound between the sixth and seventh ribs, but, at the time of the consultation, he was suffering from intestinal obstruction, which had been diagnosed as cramp colic. It was decided that a hernia of the diaphragm was present and on entering the abdomen, an opening was found in the diaphragm with a band of adhesive tissue extending up to the point where the stab wound was. A portion of the intestine was found in the pleural cavity and the adhesions were very dense. The patient came out of the anesthesia and died shortly afterward. The man who did the stabbing was declared not guilty.

Dr. MacLean, in reply to inquiry, stated that he did not think the patient died from hemorrhage. Referring to his paper and the discussion, he said it was evidently the opinion of all that an early exploratory incision should be recommended, for, although, some cases get well without operation, ninety-nine in every hundred do not.

SOME MECHANICAL CAUSES OF INTERFERENCE WITH THE ACTION OF THE STOMACH AND THEIR SURGICAL RELIEF,

by Dr. W. J. Mayo of Rochester, Minn.

The author divided the subject into two classes; first, those which act from within the cavity of the stomach or its immediate connections, such as a tumor, cicatrix, or a foreign body which may obstruct its inlet or outlet, or prevent its normal muscular action, and second, those which act from without the stomach and interfere either by pressure or adhesion, obstructing its inlet or outlet, or fixing some portion of its wall, thus preventing its functions. The main diagnostic resources are the physical examination, the distention with air, and the test-meal. The author advises Fenger's oblique left lateral incision through the abdominal walls, in order to perform gastrotomy, for the purpose of retrograde dilation; Witzel's method for temporary purposes, and Frank's spout method for permanent feeding. While for the relief of non-malignant stricture at the pylorus, he considers the Hoenke-Mikulicz pyloroplastic operation the one of choice. Two out of three operations with the Murphy button were successful, and one of the two that recovered gained forty pounds within 1½ year after the operation.

Adhesions of the pylorus or duodenum to the gall-bladder, due to the inflammation excited by gall-stones, are some of the not infrequent external causes of interference with the stomach, but the most common cause is adherent omentum. The gastric distress which almost always accompanies irreducible omental hernia of any variety will disappear after the radical cure of the hernia, and the author has seen this result in a case of a man who had suffered from gastric pain and chronic indigestion for seventeen years.

Dr. Alex. Hugh Ferguson of Chicago, in discussing this paper, said he entirely agreed with Dr. Mayo's methods of treating malignant and non-malignant stricture of the esophageal end of the stomach and with the palliative treatment that he recommends for malignant disease of this region, discarding curettment, and recommending Frank's operation as superior to Witzel's and Fenger's. He also agreed with Dr. Mayo in advising forcible dilatation in diseases of the pyloric end of the stomach and also as a preliminary step to the complete removal of the pylorus.

Section on Obstetrics and Diseases of Women.

Second Day—May 6th.

Dr. Milo B. Ward of Topeka, Kan. read a paper entitled

gauze as drainage in abdominal and pelvic surgery.

He said it was idle to say that drainage is needed only when the work has been carelessly done. However perfect the technic may be, it is still a fact that there are cases whose recovery depends entirely on the drainage employed after the surgical toilet is made. The author urged the importance of the thorough use of gauze in a large variety of complications, believing it to be the material which met the most indications.

Much had been recently said relative to the poisonous tendency of iodoform gauze when used as drainage, but he had never experienced the least untoward symptom, even when used in large quantities.

What character of cases demand gauze as drainage? His answer was almost all seriously complicated conditions of the pelvic and abdominal peritoneum, and especially when the intestines are involved, and also in all cases where the peritoneum is opened through the vagina. There were no objections to the use of rubber or glass tubes in connection with the gauze, but he had never found it necessary to employ anything but the gauze.

Dr. Howard A. Kelly of Baltimore, said he no longer drained in cases of tubercular peritonitis, and the cases practically all recovered. The cases he drains remain in the hospital an average of fifty-nine days, while those he does not drain remain on an average of thirty-nine days. The cases that were drained usually had fistulous tracks. When he does drain he uses gauze, and gave his reasons for so doing.

Dr. Chas. P. Noble of Philadelphia, said the more he operates the less he drains. Of the first hundred operative cases he had, ninety of them were drained. At the present time he drains but little. His experience has been that gauze does not drain. When he uses gauze he uses a glass tube in addition to get the fluid out from the gauze.

Dr. I. S. Stone of Washington, agreed with those who favor the extensive use of gauze.

Dr. Rufus B. Hall of Cincinnati, concurred with Dr. Noble in the opinion that gauze does not drain—at least in his own cases.

Dr. Henry O. Marcy of Boston, said that in all aseptic cases he never uses drainage, but in septic ones he does. It has been a long time since he has resorted to drainage of an aseptic wound.

Dr. George M. Sternberg of Washington, made some remarks on the destruction of bacteria in wounds.

Dr. H. O. Pantzer of Indiana, said that the peritoneum was amply able to take charge of a limited amount of pus, when the infection of tissue was not too great. He thought gauze packing was unnecessary in a great many cases. He suggests the use of peroxid of hydrogen to loosen the gauze from its attachments, where the gauze is used for drainage purposes.

Dr. A. P. Clarke of Massachusetts, said that in those cases accompanied by great loss of blood from abraded surfaces, drainage should be used, while those in which there is very little loss of blood and the patient is healthy, drainage is unnecessary.

Dr. Henry P. Newman of Chicago, said it was unnecessary to drain as much as formerly and consequently the results were more favorable. The resisting power of the structures was correspondingly great. The parts were less manipulated and influenced by trauma. This of itself meant less drainage. The speaker uses lamp-wicking as a drainage material, believing it to be superior to gauze. It can be used in large quantities. It protected abraded surfaces.

Section on Neurology and Medical Jurisprudence.

Second Day—May 6th.

Dr. Theophilus O. Powell of Milledgeville, Ga., presented an article entitled,

the increase of insanity and tuberculosis in the south.

He said the negroes of Georgia, and the South in general up to 1860, enjoyed remarkable mental and physical health, and were almost entirely exempt from certain diseases, owing to the care of their owners and the hygienic precautions taken by the latter. In 1860 there were only forty-four insane negroes in the State of Georgia, the majority of whom had white blood in them. In 1870 there were 129 insane negroes in the State; in 1880, 411 insane negroes, and in 1890, 910 insane negroes in a population of 858,815, or one colored insane to every 943 of population.

Freedom removed all hygienic restraints, and negroes were no longer obedient to the inexorable laws of health, plunging into all sorts of excesses and vices, and having little control over their appetites and passions.

Dr. Powell believed that insanity and tuberculosis were first cousins, or at least closely allied. The sudden outburst of insanity with the colored race of the South came associated with tuberculosis, hand in hand, keeping pace one with the other; the prognosis of phthisical insanity being unfavorable. Hence he is not surprised to find insanity in a family strongly predisposed to phthisis, and phthisis in a family strongly inclined toward insanity. Insanity in Dr. Powell's opinion is frequently a symptom of tuberculosis. Tuberculosis is more frequent in the insane than with the sane, and this is especially true of the colored insane.

The direct and indirect effects of syphilis is one of the leading factors in the causation of insanity with the colored race. The large number in some sections that are tainted with syphilis really is alarming. In some large plantations there are few of the adult negroes free from syphilis.

Alcoholic intemperence is another leading factor as a cause of insanity. Among negroes there is a tendency on the part of the women as well as of the men toward alcoholic excess. A distinguished alienist, writing to Dr. Powell, said "That the children of intemperate parents are liable to become insane, intemperate, epileptic, and much more liable to be congenital imbeciles."

In conclusion, Dr. Powell said: "Too much liberty and freedom, so far as the laws of health are concerned, is dangerous to the mental and physical integrity of any people."

Dr. Campbell of Knoxville, Tenn., in discussing Dr. Powell's suggestive paper, said that possibly there was a defect in it, as it did not give the statistics of insanity in various other Southern States besides Georgia. Dr. Campbell agreed that there had been a large increase in both consumption and insanity in the negro since emancipation, but thought that the statistics were probably inaccurate, because we find in the asylums now a great many of what are called "defective" classes—people who are unable to make their way against strenuous competition—whereas such individuals on the plantation were not thought insane, but were useful persons.

Dr. Campbell questioned Dr. Powell's statement that the negro race was comparatively immune to consumption before emancipation. He spoke of whole plantations being devastated by the ravages of acute miliary tuberculosis, which was then called "negro consumption."

As to the connection between consumption and insanity, Dr. Campbell thought it had not been well made out, except that both lower vitality and leave the system a prey to other diseases.

Dr. D. R. Brower of Chicago, continuing the discussion sustained by the statistics of Virginia the conclusion drawn by the latter gentleman. He said in that State, before the war, the insane negroes were gathered together in a small ward of one hospital, fifteen or twenty being about the average number, and this covering all the insane negroes of the State. Now at St. Petersburg, there is a large hospital, having about seven hundred patients. He said that as the rule is very rigid, there were not included in this number any of the "defective" cases to which Dr. Campbell referred, so that this point was not well taken.

Dr. Brower said this rapid increase of tuberculosis is a menace to the white population. Some means must be devised by which the three great factors. Dr. Powell brought out prominently tuberculosis, syphilis, and alcohol, may be done away with. A fourth factor in the production of insanity is improper food.

Dr. John Punton of Kansas City, Mo., read a paper on

THE ETIOLOGY AND PROPHYLAXIS OF FUNCTIONAL NERVOUS DISEASES.

He referred to the advance in our knowledge of the anatomy and physiology of the nervous system. Every practitioner recognizes that nervous diseases are increasing at a marvelous rate.

The entire nervous system in the normal infant and child is constantly undergoing marked changes in both structure and function. The children of neurotic constitutions should be kept fat from birth, and when they arrive at school age their brains should not be forced. A child's age should not be regarded as the criterion of its mental strength and capacity, but rather its height and bodyweight. The duty of the physician is to use all possible means to secure the needed rest for all morbid conditions of the nervous system, in which nervous irritability and nervous instability are the chief clinical criteria.

Discussion on Dr. Punton's paper was postponed.

The committee on nominations reported the name of Dr. W. J. Herdman of Ann Arbor, Mich., for chairman, and Dr. Chas. H. Hughes of St. Louis, Mo., for secretary. The report was accepted, and these officers elected for the ensuing year.

THE MEDICAL ASPECTS OF CRIME,

The next paper, was read by Dr. Albert G. Corr of Carlinville, Ill.

The brain and the nervous system are the physiological organs of the mind and intellectuality, and every grouping of ideational activity, has its origin in the functional activity of brain and nerve cells. Morality, the ethical sense, the sense of moral uprightness, has such an origin, and is subject to the same laws as the functional activities of other organs, being susceptible of cultivation, repression, or perversion.

In order to lessen crime you must cultivate and develop the moral sense and repress the emotions. Children should be taught as early as possible that there is a principle of right and justice in the abstract, irrespective of any mere religious sentiment. Every school should be required to rigidly teach them the exercise of morality, to the extent of being just and upright in conduct and character. At present, teachers too often think that morals is a theological question and not to be meddled with; and there is great room for improvement in this respect.

The moral defect with its criminal tendencies is always congenital, often hereditary, and always modified in a greater or less degree by environment and synergistic influences. The liquor traffic is the greatest dispoiler of human morals and well-being. We tolerate and perpetuate a traffic that unschools and dissipates much that our well-designed efforts have wrought. Its tendency to produce crime and make criminals is proven by history. Dr. Corr referred to Dr. Robert Boal's paper before the Illinois State Medical Association in 1894, advocating emasculation and ovariotomy as penalties for crime and as tending toward the reformation of criminals. He did not agree with Dr. Boal's conclusions, and quoted Dr. N. S. Davis' statement that he did not believe that human depravity was greatly ruled by simply the sexual organs in either sex.

THE PHYSICIAN AND THE CRIMINAL,

by Dr. J. B. Ransom, of Clinton, N. Y., was read by the Secretary.

Dr. Ransom commented upon the dearth of records as to the study of criminal man. A glance at the census figures of the United States from 1850 to 1890 shows a proportionate increase of incarcerated criminals of nearly five fold; and the number of homicides in 1889 was 3567, while in 1895 it was 10,500. He referred to the work of Sampson in America, Forbes Winslow in England, Camper in Germany, Ave Lallemant in France, and also to Drs. Arthur McDonald, Jacobi, and Flint in our own country.

The alarming ascendency of crime should excite society to vigorous effort. The modern trial, sentence, and punishment has failed. The procedures of the courts and administration of law are based upon the theory that crime must first be detected and then punished, losing sight of the fact that men are not alike, and that punitive measures should be adapted to the individual characteristics of the criminal. Crime is often the natural outcome of disease, and among its causations are arrests of growth, deformities, asymetries, intercurrent diseases, as well as psychic aberrations and disorders. Many criminals are diseased and present anomalies of structure as the cause of crime, but there are criminals who are so from environment, and from the inhumanity heaped upon them, and there are also criminals of circumstance or accident. Lombroso has shown that men with normal skulls were three times as numerous among soldiers as among criminals. This excessive abnormality among criminals extends to physiognomical, psychological, and physiological anomalies.

He estimates that twenty-five per cent. of all criminals would show disease of the heart or of the great blood vessels. It is easy to understand how a diseased heart can produce brain disturbance. Meningitis is also a prolific cause of crime. A large proportion of crime is the direct and natural outcome of some form of disease. It being conceded that crime is the result of disease, our conception of the criminal at once is such as to change the whole application of the principle of treatment. The criminal should be assisted in overcoming his misfortune. He is much like other men—amenable to treatment and improvement.

Dr. Ransom adopted the classification of Ferri, which is as follows: (1) the insane criminal, (2) the born criminal, (3) the habitual criminal, (4) the occasional criminal, (5) the criminal of passion.

As to (1), they are divided into (*a*) the paranoiac, (*b*) the psychic epileptic, (*c*) the phrenasthenic or pschopathic, (*d*) the morally insane, or reasoning phrenastheniac.

The born criminal most frequently presents anomalies of organization and psychical aberration; they are criminals, as it were, "by trade," and deficient in both moral and physical sensibility. Physical insensibility is sometimes so marked that such men exhibit no evidence of pain under the most painful operations.

The occasional criminals are such from environment and circumstances, and do not present anomalous conditions.

The criminal of passion is a highly neurotic type, and their study is of interest to the physician in that they approximate criminals of unsound mind.

The treatment of acquired and intercurrent disease of the criminal should embrace all the medical, surgical, mechanical, and therapeutical means at the physician's disposal.

Shock often causes many beneficent effects. Thus corporal punishment has often resulted in the cure of a certain psychosis. This is substantiated by statistics relative to the commitment of insane convicts to the State Hospital for Insane Convicts, which have more than doubled since the abolition of corporal punishment in the prisons of the State of New York.

This good effect extends to operations, and Dr. Ransom found that by freely cutting through the scalp, down to the bone, and raising the periosteum, great improvement followed. Two horseshoe incisions are made, five inches in length, on each side of the head, 1½ inches from the median line at the apex of the cranial arch. After separating the periosteum from the bone for about one inch all around the incision, grooves were cut in the bone, but no bone removed; the wound was packed with iodoform gauze and dressed ordinarily. Afterward, they were packed loosely until healed by granulation, no sutures being put in. In some instances the good results are marvelous.

The discussion on the foregoing papers was opened by Dr. D. R. Brower, who emphasized the importance of the subject of the Medical Aspects of Crime. He urged the profession to enlist in a crusade for the more rational treatment of crime. He favorably commented upon the custom of indeterminate sentences, whereby the criminal was induced to improve by the prospect of release added to the fear of continued imprisonment. A criminal once arrested should be kept in charge until cured, and should not be loosed upon society.

Dr. John Punton agreed with the authors and with Dr. Brower, though he suggested that the task is an enormous one, going to the root of our present institutions.

Dr. Campbell was not sanguine as to the results to be obtained by such agitation, as in his opinion this great increase of the criminal class is owing to the advance of the civilization, the multiplication of the species, and the growing stress upon the means of gaining a livelihood. He thought if all these admirable suggestions were carried out not more than five per cent. of crime would be stopped.

Dr. Powell fully agreed with Dr. Brower's statements.

Dr. Quimby thought the whole legal profession required education in the matter of treating the disease of crime, and the Church and the law having failed to repress crime, the medical profession should lend their aid in that direction.

Dr. Bishop favored radical measures, but advocated sentencing criminals for certain periods, with the proviso that if they were not improved at the end thereof, the time should be extended indefinitely until betterment.

Dr. Corr renewed his appeal to the profession to formulate some plan for the proper treatment of criminals.

The Chairman, Dr. T. D. Crothers, thought the subject a very promising one, and that we were at the be-

ginning of a great change. He hoped the matter would be brought up next year.

SOME RELATIONS OF CRIME TO INSANITY AND STATES OF MENTAL ENFEEBLEMENT,

by Dr. B. C. Allison, Matteawan, N. Y., was read by title.

Section on Children's Diseases.

Second Day—May 6th.

Dr. Henry E. Tuley of Louisville, Ky., read a paper upon

SEPSIS OF THE NEWBORN.

In this he included the report of a case in which the mother, who was a healthy woman, had been in a well-appointed hospital, and under the supervision of competent physicians and trained nurses for several weeks before confinement. The latter was normal and followed by an uneventful recovery. She had no vaginal discharge before confinement. The child was healthy until an infection occurred at the umbilicus in spite of the most carefully conducted dressings which were applied. The author made the suggestion that this case should not lead any obstetrician to relax his careful use of aseptic dressing of the cord.

Dr. A. C. Kellogg exhibited a small rubber ring that he had used and considered safer than the ordinary ligature for this purpose. Its sterilization was readily accomplished.

Dr. Parks suggested massage of large cords to reduce their size.

Dr. Cotton of Chicago, said, to prevent infection from the diaper, he used a large absorption pad, simply using the diaper as a means of retaining the latter in place.

The subject of

CHOREA

was introduced by a paper by Dr. Henry Hatch of Quincy, Ill. He believed the nervous affection was directly due, in the majority of cases, to the modern faulty methods of rearing and educating girls, especially. He suggested a modified rest treatment, combined with tonics of which rapidly increasing doses of strychnia.

Dr. W. A. Dixon of Ripley, O., mentioned the frequency of cardiac complications in chorea.

Dr. Callan spoke of the difficulty of obtained necropsies upon uncomplicated cases of this disease, and mentioned fright as one of its etiologic factors. The patients were usually anemic, and showed a diminution of hemaglobin. Arsenic was a good tonic and alleged specific.

Dr. Hatch, in closing the discussion, emphasized the beneficial influence of strychnia upon these cases.

General Session.

Third Day—May 7th.

Dr. E. E. Montgomery of Philadelphia, read the report of the Board of Trustees of the Association, which showed a total balance of $10,084.98. The Board considers this a most excellent showing, considering the financial condition of the country and the radical change in the policy of the *Journal* instituted at the last meeting.

The Board placed on record their appreciation of the valuable services of their late colleague. Dr. James E. Reeves, and their deep regret at his untimely death.

On motion the report was adopted.

Dr. George H. Rohé of Maryland, in the absence of Dr. A. L. Gihon, read the report of the Rush Monument Fund Committee, which, on motion, was received and filed.

The Nominating Committee made a partial report, viz., the place of meeting, recommending Philadelphia, time, first Tuesday in June, 1897. Unanimously adopted.

Dr. H. D. Holton of Vermont, offered to be one of the forty to give $100 toward the Rush Monument.

On motion of Dr. Holton the trustees were authorized to establish a building fund.

Vice President Dr. J. C. Le Grand, then took the chair and Dr. Nicholas Senn of Chicago, delivered the address in surgery. (See page 507 of last weeks issue.)

On motion of Dr. MacLean of Detroit, the thanks of the Association were tendered to Dr. Senn for his masterly address.

The secretary read his annual report, which contained nothing of special interest. On motion it was adopted.

The following preamble and resolutions were offered by Dr. Senn, Chairman of the Committee on Vivisection in the District of Columbia.

Whereas, The members of the American Medical Association recognize the fact that the development of scientific medicine has resulted largely from experiments upon the lower animals; and,

Whereas, Anesthetics are habitually administered to animals subjected to painful experiments; and,

Whereas, Restrictive legislation is in our opinion unnecessary and opposed to the continual progress of medical science; and,

Whereas, It is an unjust reflection upon the humanity of those engaged in animal experimentation to enact laws requiring them to use anesthetics and appointing inspectors to see that they do so, and,

Whereas, Far more unnecessary pain is constantly being inflicted upon the lower animals for sport and for game than in biological and pathological laboratories; and,

Whereas, No evidence has been presented by those who advocate restrictive legislation showing that abuses exist in the District of Columbia; and,

Whereas, Results of great practical importance have been attained by experiments on the lower animals made in the Government Laboratories in the District of Columbia; therefore be it

Resolved, That the American Medical Medical Association earnestly protests against the passage of Senate Bill No. 1552, entitled, "A Bill for the Further Prevention of Cruelty to Animals in the District of Columbia," or any modification of this Bill, unless it shall first be shown by an impartial investigation that cruel and unnecessary experiments are being performed in the District of Columbia, and that existing laws do not provide suitable punishment for cruelty to the domestic animals.

Resolved, That copies of these resolutions, attested by the signatures of the President of the American Medical Association and of its committee appointed to draft these

resolutions, be sent to the chairman of the committees in the District of Columbia in the House of Representatives and Senate of the United States.

(Signed) NICHOLAS SENN,
WILLIAM OSLER,
GEORGE M. GOULD,
J. MCFADDEN GASTON,
DONALD MACLEAN.

On motion of DR. E. D. FERGUSON of Troy, N. Y., the resolutions were adopted.

On motion of Dr. Westmoreland, the program for the Jenner Centennial Memorial was made the order of business for to-day.

The SECRETARY read the following from the New York County Medical Association:

Resolved, That this Association declares its continued attachment to the Code of Ethics of the American Medical Association, and deprecates any management of the affairs of that Association except by the various State and County Associations and Societies in affiliation therewith, by their regularly appointed delegates.

Resolved, That delegates appointed by this Association to the meeting to be held in Atlanta, Ga., be instructed in accordance with this action.

On motion the resolutions were received and filed.

DR. H. D. DIDIMA, New York, read the address of DR. N. S. DAVIS of Chicago, this being the opening paper of the Jenner Centennial.

DR. C. S. MCGAHAN, Minnesota, read for DR. C. N. HEWITT of Red Wing, Minn., his paper entitled

A TRIBUTE TO THE MEMORY OF EDWARD JENNER,

by title.

DR. J. COCHRAN, Alabama, followed by reading a paper, the title of which was not given.

DR. GEORGE M. STERNBERG of Washington, read a paper entitled

SCIENTIFIC RESEARCHES RELATING TO THE SPECIFIC INFECTIOUS AGENT OF SMALLPOX AND THE PRODUCTION OF ARTIFICIAL IMMUNITY IN THIS DISEASE.

DR. DIDIMA presented by title a record by DR. D. H. STORER, Rhode Island, of

THE MEMORIALS, MEDALS, ETC., OF EDWARD JENNER.

DR. F. C. MARTIN, Massachusetts, read a paper on

THE PROPAGATION OF VACCINE VIRUS.

DR. EUGENE FOSTER of Augusta, Ga., read a voluminous and valuable paper on

THE STATISTICS OF VACCINATION.

On motion of DR. J. F. HIBBERD, Indiana, it was

Resolved, That the papers read at this Jenner Centennial Celebration be referred to the Jenner Centennial Committee for revision and selection of those deemed proper to be published in book form and in such number as the committee may believe there will be demand for.

On motion of DR. DIDIMA the thanks of the Association were tendered to the writers of the papers.

Adjourned.

SECTION ON SURGERY AND ANATOMY.

THIRD DAY—MAY 7TH.

LIGATION OF THE EXTERNAL CAROTID ARTERY.

by WILLIAM PERRIN NICOLSON, M.D., Atlanta, Ga.

This operation was done in conjunction with exsection of the jaws and of the inoperable diseases of the same.

DR. PARKER of New Orleans, in discussing this paper, said: "My experience in ligation of the external carotid has been very limited and I have never seen such a good effect from the operation in reducing the size of a foreign growth as that mentioned by the author. I agree with him in the knot he employs, but with regard to the suture, I have been using kangaroo in preference to catgut.

DR. EDWARD SOUCHON wished to warn one to be very careful in tightening the ligatures; otherwise, the coats of the artery will be ruptured and a secondary hemorrhage result.

DR. NICOLSON, in closing the discussion, said: No one could be more surprised than I was at the prompt and extensive effect upon the foreign growth by the ligation of the artery. Although the operation is usually a very bloody one, ordinary sponging will always control the hemorrhage. It is well to ascertain with the finger when the circulation has been controlled as one can thus avoid the risk of rupturing the coats of the artery.

THE TECHNIC OF REMOVING THE APPENDIX VERMIFORMIS CECI.

Report of one hundred cases by DR. M. M. JOHNSON of Hartford, Conn.

The author described the method of preparing the patient for the operation, which he is in the habit of employing in this operations. He spoke at some length concerning the incision to be made and considered that the statement of Dr. Morris, "An inch and a half and a week and a half" contained a sound surgical principle to go upon. He also strongly advised as little manipulation as possible of the intestines. In chronic recurrent cases he made an incision one and a half inch long directly over the appendix, and when the peritoneum is reached a catgut suture is passed through it at the upper angle of the incision, so as to prevent its retraction. In finding the appendix he passes the thumb and index finger through the incision, seizes the colon, which he draws through the incision until the appendix is brought into view. When the cecum is surrounded with a pus sac, a perforated and sloughing appendix is usually found and should be removed. It should be a fixed rule never to close up the incision without finding and removing the appendix. The treatment of the stump resolves itself into the treatment of an intestinal perforation and the surgical rule for the treatment of this condition should not be violated in the treatment of the stump.

In closing the incision we are justified in assuming that the various layers of tissue are arranged in the best possible order and the work of nature should be respected by leaving them as nearly as possible as they are found. By making gentle traction on the catgut-suture passed through the peritoneum at the upper angle of the incision, the retraced peritoneum is brought into view, and with a

Martin needle, loaded with No. 2 catgut, a stitch is easily passed through the free borders of the peritoneum and the edges drawn together. By removing the original suture and making gentle traction on the last stitch enough more of the peritoneum is drawn into the incision to take another stitch, and this is continued until the peritoneal incision is closed by a continuous catgut suture. The transversalis Fascia and transversalis and internal oblique aponeurosis is secured by a continuous suture separately. The skin is put hard on the stretch by a tenaculum placed in the angles of the incision and the edges are united with No. 0 (zero) catgut in a fine needle. The author has never had a case of hernia following this method of closing the incision. Catgut is used throughout the entire operation which is sterilized by the author himself.

With regard to the time for operation this should be decided from the standpoint of the best interests and safety of the patient. In the author's opinion, operative measures should be an early consideration rather than the last resort. Of 100 operations performed by Dr. Johnson, 98 resulted in recovery and 2 in death, of which number 64 were males and 36 females.

Dr. Parker of New Orleans, in discussing this paper said: I cannot agree with the author as to the advisability of at all times removing the appendix, and think that in those cases where the appendix is surrounded by an abscess, all that is necessary is to open the abscess and drain the region.

The Secretary, in discussing this paper, said: I fully agree in Dr. Parker's remarks, and have not encountered a single recurrence after this method has been employed. I think each case should be treated entirely on its own merits.

Dr. Alex. Hugh Ferguson of Chicago, in discussing this paper, said: I do not wish to discuss this paper, but would like to say that I consider the most favorable time to operate between the attacks, and I believe it dangerous to operate during the acme of the inflammation. With regard to the length of the incision, in ninety-nine per cent. of the cases an inch and a half and a week and a half is wrong. The best way of draining in these cases is with gauze and a glass-tube.

Dr. Haines of Omaha, said: I consider the routine practice of removing the appendix one to be condemned.

Dr. Johnson, in closing the discussion, said: When the appendix is situated in the wall of a pus sac, I think it should always be removed and I have never yet had a case of peritonitis resulting. I do not think a seven-inch incision should be required in any case, and some experience will enable one to perform the operation through a very small incision.

WHO WAS THE FIRST TO ILLUMINATE THE SIGMOID CAVITY?

by J. G. Carpenter, Stanford, Ky. This paper was not discussed.

ON THE EXPLORATION OF THE BRAIN WITH A NEEDLE AND SYRINGE THROUGH CAPILLARY HOLES DRILLED THROUGH THE SKULL,

by Edward Souchon, M.D., New Orleans, La.

This method is proposed to take the place of trephining, *i.e.*, removing a ring of bone before exploring the subdural spaces and the brain. The simplicity of the procedure and its safety recommends it as an easy means within the reach of a greater number than the other comparatively more serious and complicated operation of the trepan. By its ready employment it is expected that many lesions, especially abscesses, cysts, and hard tumors can be earlier diagnosed and located with certainty after exploring by this means the region suspected from the distant symptoms. It is only in cases of tumors of the same consistency as the brain, that is soft but not fluid, that the explorations would be of no avail, but this would also be the case if the trepan had been used instead of the drill. Even then, in some cases, the microscopical examination of the particles expelled from the needle might give reliable information. The *modus operandi* is most simple. Spots of the scalp are disinfected; a puncture is made with a sharp bistoury down to the bone. The drill employed is an ordinary stem watchmaker's drill to which is added an adjustable guard to prevent unlimited penetration of the drill into the brain substance after penetration of the bone. When the inner table is reached the drill is worked more cautiously. The perforation of the skull is easily completed with the point of a No. 1 aspirator needle attached to a syringe. All must be done under thorough asepsis and according to the rules followed in exploring after ordinary trepanation. Several holes can be drilled at a distance from one another, at the same time. Apprehensions have been expressed as to the danger of hemorrhage, but the writer cites experiments made by himself on dogs whose brains were several times explored at several places at each sitting and which never exhibited any symptoms of hemorrhage. One of the dogs was killed and no trace of hemorrhage worth mentioning was found. He reports also *post-mortem* examinations by Spitzer, Meinchard, and Schmidt, of cases where the subject had succumbed from the natural course of the original disease and where no traces of hemorrhage were found.

Dr. Thomas H. Manley of New York, in discussing Dr. Souchon's paper, said that, except in very exceptional cases, he was unable to agree with Dr. Souchon as to the value of the needle in the exploration of the brain.

Dr. Nicholas Senn of Chicago agreed with Dr. Manley, but thought the needle might be of some service when combined with a temporary resection of the skull or when such pathological productions as blood, serum, cysts, or abscesses were present.

Dr. Alex. Hugh Ferguson of Chicago had not found, in his experience, that the use of the needle was a reliable method.

Dr. Souchon closed by stating that the two important things to bear in mind was the size and the cleanliness of the needle.

SURGICAL SHOCK; A NEW TREATMENT, WITH DEMONSTRATIONS,

by Dr. Fenton B. Turck, Chicago, Ill.

The author gave a practical demonstration of his method of treating surgical shock, and mentioned the result ob-

tained in a few of the twenty-three experiments he had performed.

This paper was not discussed.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

THIRD DAY—MAY 7TH.

DR. A. P. CLARKE of Cambridge, Mass., read a paper entitled

DEGENERATIVE CHANGES THAT OCCUR IN UTERINE FIBRO-MYOMATOUS GROWTHS,

by DR. AUGUSTUS P. CLARKE, of Cambridge, Mass.

The author begins by saying that the presence of uterine fibroid growths has for the past few years given rise to much discussion among gynecologists; the consideration of the surgical treatment which they have demanded has received much attention and measures of procedure, in some instances apparently opposite, have sometimes been adopted. The success attending the removal of fibroid growths either by partial or by total hysterectomy has brought the subject of such neoplasms more prominently before the profession. This has stimulated to such an extent a desire for greater knowledge concerning them that only the most careful clinical experience and pathological investigation will be found to be capable of furnishing the data necessary to determine the proper solution of the question. Late experience has shown that certain pediculated subserous fibroids in taking on retrograde processes become harder and more unyielding from the presence of the excess of the fibrous element and from the occurrence of calcareous deposits that may take place in the tissue of the morbid mass. Fibroids in such a condition may exercise a pressure that may result in renal and in other complications.

The author mentions as coming in his own practice cases that, besides giving rise to hemorrhage, have the history of such sequelæ. Contraction from various causes and the consequent cutting off of the arterial supply may lead to suppurative changes and liquefaction of the tumor. Gangrene is another result that may occur. This may lead to a general septicemia of the organism. Cases illustrative of these conditions are mentioned. Fibroids though liable to increase from excitation of the menstrual periods and from pregnancy, especially those of the submucous variety and those akin to the myxomatous class, may nevertheless undergo marked diminution after parturition. The author doubts, however, whether such growths ever wholly disappear; they may for indefinite periods remain unaffected but they are liable to become the foci of malignant degeneration. The author further says that the record of cases coming in his own practice shows unmistakably that the malignant degenerative changes to which these growths are prone are not of rare occurrence. The favorite haunt of uterine cancer is in the cervix uteri; it often shows its development in the fissures of the lacerated portion. From this center the morbid process may radiate and extend to the upper segments of that organ. The characteristic symptoms of the disease with the cachexia of malignant invasion are early accompaniments. He says the presence of malignant disease in cases of fibroids is not a mere complication, but he holds to the view that it is a degenerative change.

In presenting a contrast of the two conditions he says that in malignant degeneration of fibro-myomata the morbid processes leading to the development manifest other aspects. The early appearance of fibroids may not be attended with any definite constitutional peculiarities. There will be no facies of a distinctive type; except for the results that may be attendant on metrorrhagia or menorrhagia, the occurrence of the irregular outline of the growth and the consequent pressure or other annoyances experienced, the patient may have the appearance of being in almost perfect health. In the unmarried or in those who have not suffered from cervical laceration the lower section of the uterus may be entirely free from the morbid invasion. The freedom in this part of the uterus may continue after a fibroid has assumed malignant phases and until the development has extended downward.

Aneurismal and also fatty degenerative changes are spoken of and discussed at some length. Another form which has a practical significance to the abdominal surgeon is that resulting from the occurrence of enormously enlarged vessels or capillaries; these vascular elements may develop at the expense of the connective and the muscular tissues. The occurrence of these telangiectatic myomata may be a fruitful source of hemorrhage and thus threaten or destroy the life of the patient. Early surgical interference offers the best means for relief, so also does such surgical treatment in cases of myoma lymphangiectodes which occasionally occur. Inflammation in the tissue of a fibroid may extend to the arterial coats, producing arteritis, and lead to the obliteration of those vessels. Colloid degeneration may take place in the deeper portions and may give rise to conditions similar to those in which the tumor becomes liquefied. In many fibroids the vascular element is not plentiful. The capillaries in some of the forms are prominent while in others special artificial injections that are carefully made show that but few vessels permeate the mass. The irritation and hyperemia with which the adjacent mucosa may be subjected are the cause in some instances of the hemorrhage. Calcification of fibro-myomatous growths, as already referred to is an occasional sequel; so also is the production of tissue-resembling cartilage, which, as a secondary result, has occurred in the mass. One of the most frequent transformations which, without doubt, fibromyomata may undergo is their contraction and atrophy after the cessation of their normal development. Myxomatous changes and submucous alteration tend to the destruction of the growths. The intra-parietal contractions to which they are subject serve to hasten the production of polypi and the commencement of extrusion from their normal sites. All these several kinds of secondary transformations occurring in fibro-myomata are productive of further expulsive processes that often require only timely surgical interference as measures supplementary to the effecting of their complete removal.

DR. CHAS. P. NOBLE of Philadelphia, read a paper entitled

DRAINAGE VERSUS RADICAL OPERATION IN CASES OF LARGE PELVIC ABSCESS.

The object of the paper was to call attention to the value of drainage in the treatment of large pelvic abscesses, and to contrast the results which can be secured by this method of treatment with those which have been obtained by the more radical operation of abdominal section, together with the removal of pus sacs, whether of ovarian, tubal, or other origin. An ordinary case of pyosalpinx, or abscess of the ovary, chronic in character, was ruled out of consideration. The paper dealt only with those cases of extensive suppuration in which, in general, in addition to pyosalpinx, or abscess of the ovary, there exists an intraperitoneal abscess or abscesses, and in which the pelvic viscera are matted together by extensive exudate, and in which very frequently at the time the patient comes under the observation of the surgeon, active inflammatory or septic processes are going on, which have confined the patient to bed for weeks and probably months, so that she is greatly reduced in strength and vigor, and but little able to resist the shock of a serious surgical operation.

Until June 11, 1895, the author had never employed drainage without abdominal section in the treatment of this class of cases, but had always operated on them by abdominal section and the removal of the diseased parts. Since this period the speaker had operated upon eight cases, each of whom was a typical and very marked example of the class of cases under consideration, by simple drainage without death. Seven of these women had been critically ill at the time of the operation. They had been confined to bed with septic fever from three to eighteen weeks, and he felt certain that if operated upon by abdominal section, at least six of the eight would have died of shock of septic peritonitis.

SOME SUGGESTIONS IN THE PROPHYLAXIS AND MANAGEMENT OF PUERPERAL ECLAMPSIA.

This paper was read by Dr. H. D. Thomason of Albion, Mich. He first dwelt upon the pathology and etiology of puerperal eclampsia, saying that it was still an unsettled question. As soon as he is satisfied of the viability of the child, he believes he is not only justified, but it is his duty to bring about premature labor, *first*, upon the ground of safety, welfare and comfort of the mother; *second*, for the welfare and safety of the child. A case coming under the author's observation was reported as an illustration.

Dr. Henry O. Marcy of Boston read a paper entitled:

INTESTINAL OBSTRUCTION AFTER LAPAROTOMY.

Before entering into a general discussion of this subject the author gave a brief report of all the cases of intestinal obstruction following laparotomy which had come under his observation. He reported seven cases.

The portion of the intestine involved in the obstruction in each case was the lower part of the ileum, and that the obstruction was caused either by an adhesion of the intestine to an infracted peritoneal surface, or by a constriction. In three of the cases reported, two of which were fatal, the intestinal obstruction occurred from incarceration of the lower portion of the small intestine, caused by adhesive bands of old formation. In the two fatal cases a laparotomy had been performed some years previously, and although in both they were non-suppurative cases, adhesions had formed, probably caused by undue pressure of opposing peritoneal surfaces, owing to pathological conditions.

The history of the cases teach a wide difference in the acuteness and severity of symptoms from that of intestinal obstruction, as usually noticed in volvulus or strangulation resulting from hernia. After outlining the treatment for the relief of the obstruction, Dr. Marcy emphasized the practical importance of the preparation of all patients for laparotomy. The condition of the nervous system is important. The lowering of the nervous tension is a very great gain. The substitution of hope for fear and confidence in the outcome is of much more value than he was earlier constrained to believe, and why should not this be true, since the best definition of life itself is the equilibrium of the vital processes in their sway over the organic matter which they hold in control.

Intraperitoneal surgery must ever be of the highest order and accuracy and completeness of detail must go hand in hand in every process to prevent infection. Where these great surgical laws have been complied with, recovery is in direct ratio with the minimizing of the devitalization of the patient. These are the almost ideal results to which modern surgery has already attained, and upon their practical application depends the marvelous success of the surgeon of to-day.

Dr. E. E. Montgomery of Philadelphia, followed with a paper entitled

PUERPERAL SEPSIS, ITS PROPHYLAXIS AND TREATMENT.

Dr. R. R. Kime of Atlanta, read a paper entitled

PUERPERAL INFECTION, ITS PATHOLOGY, PREVENTION, AND TREATMENT.

The author stated that prevention of puerperal infection is accomplished by strict asepsis in obstetric practice, as well as thorough emptying of uterus and securing proper contractions with repair of lacerations.

Dr. Albert H. Burr of Chicago, read a paper on

GONORRHEA IN THE PUERPERIUM.

The author confesses to a feeling of insecurity in every case of approaching confinement, where he knows beforehand, or has reason to suspect the existence of gonorrheal infection, either active or latent. In an obstetrical experience of five hundred cases he has had three fatalities, each of which is directly traceable to gonorrhea. In many of the remaining cases of puerperal sepsis, more or less severe, he had found by clinical history or by microscopic verification, the presence of a gonorrheal infection.

Dr. Burr stated that it would be a righteous advance when the State affords some protection to the innocent by placing legal barriers to the matrimony of all individuals who, by competent medical inspection, cannot present certificates of freedom from all contagious and hereditary

diseases. Nor should the line be drawn on the male sex only.

HYSTERECTOMY AS AN ACCOMPANIMENT TO BILATERAL REMOVAL OF THE APPENDAGES.

This paper was read by DR. REUBEN PETERSON of Grand Rapids, Mich.

The author made a plea against the adoption of the universal rule in regard to these cases as if it were for all time settled. He claims that the surgeon has no right to remove the uterus after removal of the appendages unless he is convinced that the organ is diseased beyond the hope of cure by less radical methods.

DR. MILO B. WARD of Topeka, Kan., was elected *Chairman* of this section, and DR. GEORGE H. NOBLE of Atlanta, Ga., *Secretary*.

SECTION ON NEUROLOGY AND MEDICAL JURISPRUDENCE.

THIRD DAY—MAY 7TH.

The topic before the Section on Neurology and Medical Jurisprudence was

MEDICAL EXPERT TESTIMONY.

The first paper was entitled

PROPOSED REGULATION OF MEDICAL EXPERT TESTIMONY,

and was read by DR. A. WALTER SUITER, of Herkimer, N. Y., who described the present method of expert testimony as ridiculous. Specialists of the most extended experience should alone be permitted to testify; indeed, expert witnesses should in all cases be officers of the court, and independent of the parties to the suit,

Dr. Suiter advocated the appointment of a Commission of Experts by the court to decide all such questions as should be submitted to them; also, the establishment of an educational curriculum, defining the requirements necessary before a physician is allowed to occupy the position of expert. He also said that members of such commissions should be allowed a just compensation, to be paid by the county. He gave the draft of a bill which it is proposed to shortly introduce into the New York legislature.

The next paper,

INSANITY IN COURT,

by DR. L. HARRISON METTLER of Chicago, Ill., was read by title.

EXPERT TESTIMONY IN DISPUTED CASES OF INEBRIETY,

was the title of an article read by DR. T. D. CROTHERS, Hartford, Conn., in which he emphasized the importance of alcohol as a factor in the production of insanity, and the fact that when a man, after a long history of debauchery, committed some crime for which there was no apparent reason, there was a strong likelihood of his insanity; that in the determination of insanity the entire history of the case should be taken into consideration, and the expert should not be limited to what the patient actually said or did at or about the time of the commission of the act in question.

DR. DANIEL R. BROWER of Chicago, Ill., then presented a paper upon the

NECESSITY OF REFORM IN MEDICAL EXPERT TESTIMONY.

in which he set forth the defects of the present system and urged that the medical profession unite in an attempt to secure some much-needed changes.

The discussion on the foregoing papers was opened by DR. CHARLES H. HUGHES of St. Louis, Mo., who said: The question of expert medical testimony is a far more difficult question to determine by legislative enactment than at first blush appears. The chief difficulty in the whole question is the quality of the expert testimony itself, which should be improved.

In cases of insanity we are enabled by careful interrogation of the patient to establish the systematic evidences of disease in the individual's brain, just as we determine disease in the body, because mental disease, like disease in any other region, obeys certain laws. The departure from the states of feeling and modes of thought, usual to the individual when in health, can generally be placed very plainly before a court by experts, so as to bring conviction to the average jury, and reflect a reasonable amount of credit on our profession.

DR. HAROLD N. MOYER, Chicago, Ill.: The subject may be divided into the mischief and the remedy. As to the first, the present system is not nearly so bad as has been stated. The defects of the system are more or less inherent in the constitutions of society and human individuals themselves. Again, medicine is not an exact science. On some subjects there are wide divergencies of opinion.

The remedies are divided into two clases: (1) the continental system, limiting the function of the jury who must accept the experts' decision as to the matters referred to them as final; (2) simply changing the manner in which experts are summoned, and obviating as far as may be bias among them. Of course, it would be advisable to rob experts of all partisan feelings and tendencies, making them experts of the court, not of the plaintiff or defendant. Dr. Crothers carries his opinion as to the effect of inebriety too far in Dr Moyer's opinion,

DR. ROHÉ: It was suggested in Maryland to authorize the court to appoint a commission of three physicians qualified and advanced in medical science, and experienced in the treatment of insane persons, who should examine the individual personally, hear the testimony, if any, and report to the court under oath their findings; the court to have power of discharging the commission, or if desired, reverting to the old form of inquiry by jury. Such a commission should only be allowed in criminal cases.

DR. H. O. MARCY, Boston, Mass.: Massachusetts suffers perhaps more than any other State from the present conditions. The best men in Massachusetts will not appear as experts in courts.

DR. H. S. DRAYTON of New York: This matter has been under consideration in New York City, by both physicians and lawyers, for four or five years. A commission appointed by the court in each case seems to be favored. Dr. Drayton referred to the Carlyle Harris case,

in which many eminent experts were so seriously treated. He said there had been a number of instances of insistence upon a categorical answer, but that the physician should always insist upon qualifying his response. He advised giving written opinions.

Dr. Bishop of Pennsylvania: If one is asked a question and required to answer yes or no, all that one need do is to say "I don't understand." Medical experts are sometimes inclined to make speeches on the stand and this tendency gets them into trouble.

Dr. Moyer: None of us have ever favored a permanent Commission or the Continental System. The best method is the appointment of separate experts by the court for each case.

Dr. Suiter, of Herkimer, N. Y.: We are eager to receive suggestions. As to the method of appointment, everyone is agreed that the appointment should be made by the court and the county bear the expense.

Dr. Harold N. Moyer then made a few remarks on the

MEDICO-LEGAL SIGNIFICANCE OF THE SKIAGRAPH.

saying that it had only come into court on two occasions, and then was readily admitted. He referred to the use of the skiagraph in determining the difference between genuine and imitation gems, and he also showed a large number of interesting skiagraphs which had been made use of preliminary to operative procedure.

Dr. W. J. Herdman also discussed the Rontgen rays, illustrating his statements by drawings on the board.

Dr. G. W. Drake of Chattanooga, Tenn., said the great question now is how to make pictures more quickly, and this is being attained very rapidly. We want to get so that we can put the fluoroscope to the eye, and learn diseased tissue from normal tissue by relative opacity!

Dr. H. O. Marcy of Boston, Mass., read a paper on

HERNIA FROM A MEDICO-LEGAL STANDPOINT,

and spoke of the necessity of proper operation in cases of hernia, because sins of omission were just as grave as sins of commission. He wished to impress upon the profession the requirements of this large class of patients.

Dr. Moyer expressed his gratification at Dr. Marcy's addition to the literature on this point, which he thought was somewhat scanty.

Dr. Hughes said he had always been under the impression heretofore that accident was a frequent cause of hernia, but he would, of course, defer to Dr. Marcy's judgment on this point,

Dr. Bishop thought the paper would be of value in laying stress upon the fact that operation in hernia is comparatively safe and the danger from no operation much greater.

General Session.

Fourth Day—May 8th.

The Treasurer, Dr. Henry P. Newman of Chicago, read his report, showing a healthy condition of the treasury.

On motion the report was adopted.

The address on

STATE MEDICINE

was then delivered by Dr. Geo. H. Rohé of Maryland. (See page 510 of last week's issue.)

Dr. Bulkley of New York, from the Executive Committee, offered the following:

The Executive Committee report the following resolutions and recommend their adoption:

Resolved, That in accordance with the standing rule of the Association, the Committee of Arrangements for the next session is requested to arrange the meetings of the Association and prepare the program for the sections so that they will not conflict. It is suggested that if the general sessions on Wednesday and Thursday be called at 11 o'clock it may remedy the evil.

Unanimously adopted.

Resolved, That the committee of arrangements for next year, and hereafter, be directed to prepare signs for each State and Territory, also for the District of Columbia, and the Army, Navy, and Marine Hospital Service, and to locate them in the hall of meeting that the delegates shall meet beneath them for the selection of members of the nominating committee.

Resolved, That the elections for such members of the nominating committee shall only be legal when held in these localities.

On motion of Dr. Love, this was laid on the table.

The following amendment was offered by the business committee:

Resolved, That there be made an executive council of five, consisting of the three officers of the executive committee and two officers chosen by election. Of this council of five, one must belong to the Section on Practice of Medicine and one to the Section on Surgery and Anatomy. To this executive council shall be delegated all the duties of the executive committee during the intervals between its meetings. (Laid over for one year.)

Dr. Alonzo Garcelon of Maine, offered the following resolution:

Whereas, This association has authorized the trustees to establish a building fund, and whereas the question of a permanent location for the *Journal* has never been decided by a vote, therefore be it

Resolved, That the trustees be, and are hereby instructed, to cause a vote by ballot to be taken, and on this question all members shall have the right to vote. The ballots may be received from and after June 1st until July 31st, when the ballot shall close. No ballot shall be counted in favor of any particular place, unless the name of the member voting shall be signed thereto. The ballot shall be preserved by the trustees until the next annual meeting of the association, but the result shall be published in the *Journal* when the count shall have been completed.

The resolution was adopted.

Dr. J. Cochran read the report of the Committee on National Department of Public Health, which on motion was adopted, the committee enlarged to include a member from each State, and continued:

Dr. Senn, Chairman of the Committee on President's Address, presented the following resolution:

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXVIII. NEW YORK, SATURDAY, MAY 23, 1896. NO. 21.

ORIGINAL ARTICLES.

ASEXUALIZATION IN THE PREVENTION OF CRIME.

BY G. FRANK LYDSTON, M.D.,
OF CHICAGO;
PROFESSOR OF SURGICAL DISEASES OF THE GENITO-URINARY ORGANS AND SYPHILOLOGY IN THE CHICAGO COLLEGE OF PHYSICIANS AND SURGEONS; FELLOW OF THE AMERICAN ACADEMY OF SOCIAL AND POLITICAL SCIENCE.

AMONG all of the advances in sociologic science which may fairly be attributed to modern scientific medicine, nothing is more prominent than the philosophical treatment of the crime question. The attempt to reduce criminology to a rational and materialistic basis has constituted a great step in advance—one which marks a distinct epoch in scientific sociology. The science of criminology is comparatively new, and its study, in this country particularly, has only recently become popular. But it is my impression that just at the present moment the study of criminology needs to be saved from some of its over-enthusiastic friends and from the misdirected zeal of certain *dilettante* scientists and alleged criminal anthropologists. The second exception which I would take to the trend of scientific thought upon the crime question is that we are too much concerned with the criminal of to-day or the cure of the individual criminal, rather than with the very remote conditions which produce criminality in him, and which conditions will inevitably produce criminality in his descendants, as well as in many individuals who are more or less remotely related to his criminal stock.

In the consideration of the theme which I take the liberty of presenting herewith, it will be necessary to indulge in some general considerations of the causes of, and remedies for, crime. In the first place, the proposition is advanced that society is responsible for its own criminals, and in a less degree for its paupers, inebriates, and insane. These are the flotsam and jetsam of the social stream. They are, so to speak, the excreta of society, the retrograde products of social metamorphosis, bearing the same relation to the social body that certain excrementitious products of physiological metamorphosis bear to the animal body. The sources of these products should be considered, and the aberrations of the social body which produce them corrected, else no measures of repression of resultant evils are likely to be successful. I believe that the conditions producing these excrementitious social products are more amenable to measures of correction, and less inevitable, than what I have presumed to term the analogous conditions in the human body. In the case of the animal body, we are aware that certain excrementitious products of physiological change are absolutely necessary. We, however, deny the necessity of allowing these products to remain in the animal body and contaminate it or be placed in a position to injure other animals after discharge from the body. Is not the same true with regard to the social body? All of the conditions which produce the criminal class are furnished by society. Society's method of cancelling its debt is to punish the criminal after he has arrived at a point at which he menaces the safety, comfort, and commercial interests of society. At no time before, is cognizance taken of the results of the poisonous stream of criminality as it sweeps through some particular part of the social system, and an attempt made to correct them. Is this logical? Would it not be far better to turn the stream harmlessly aside, dam it at its source and antidote its contained poisons, if such a course be possible?

Society begins its self-contamination at the marriage-license window. The foundation-stone of society is the matrimonial relation. Its assumption is the most important step that a human being can possibly take, and upon the conditions which surround it depends some of the most important interests of our social system. Taking this into consideration, and laying aside the interest of the individual, is it not surprising that no effort at the regulation, control, or supervision of the marriage relation is made by society? The license-window is a place where the honest citizen and the criminal, the sane and the insane, the diseased and the healthy, the pauper and the millionaire, the learned and the ignorant, may meet upon common ground—for the important consideration of $1.50. The criminal, the insane, the epileptic, the syphilitic, the consumptive, and the drunkard are legalized to go on producing their kind, the number of their progeny being limited

entirely by the sweet will and physical capacity of the individuals. That the product of the factory of degenerates set in operation by licensing such people, is a menace and a burden to society goes without the saying. Has society a right to protect itself against its own vicious offscourings? I believe it has. I think the time will come when it will be no longer possible for our army of degenerates to procure licenses to marry. *I believe that it should be, and one day will be, a crime for a person in the active stages of venereal disease to marry and almost invariably infect innocent persons.* There can be no greater crime against the individual than inoculation with contagious disease—a disease which, perhaps, may outlast several generations and carry affliction to unborn innocence.

I am well aware that sentiment is strongly against the regulation of matrimony, still, sentiment has been no bar to the demand for a license and for the performance of the marriage ceremony by the proper parties afterward. Why should it be a bar to demands for proper qualification on part of the prospective candidates for matrimony? To reduce the question to its ultimate by very material and substantial argument, society should govern matrimony upon business principles. It should protect itself against the danger and expense of breeding an army of paupers, lunatics, criminals, and diseased persons. A life insurance company which should be governed by sentiment, would not be very highly regarded from a business standpoint, nor would it be likely to endure. Why should not society handle this question from the standpoint of a huge co-operative insurance association?

The prospective criminal once born, what does society do to prevent his becoming a criminal? Practically nothing. The child of poor but honest parents, is allowed to run the streets and contract evil habits or vicious associations. Result, eventually a criminal or a prostitute in a large proportion of cases. The child with hereditarily criminal propensities is allowed to follow the same course. The diseased degenerate child, whose parents are unable to care for it, is allowed to be exposed to all manner of vicissitudes, and unless fortunate enough to be cut off by death at an early period, eventually becomes a burden upon the community. What is the remedy at present instituted for this condition of affairs? Society punishes the vicious child after a criminal act has been performed, and sends the diseased one to a hospital to be supported by the public after he has become helpless. Even today, the child who has committed its first offense is thrown by the authorities into contact with older and more hardened criminals—to have its criminal education completed. We have millions for sectarian universities, millions for foreign missions, but no dollars for the redemption of children of vicious propensities or corrupting opportunities, who are the product of our own vicious social system and should be the wards of the State. But this is expensive. Yes, possibly,—for the time being,—but within a few generations a diminution in expensive processes of law and of costly penal institutions, would make the plan a most economic one in the long run.

A very important factor in the development of the criminal class is the fact that crime seems to be quite profitable; that the gigantic swindler, if he be successful, wins a greater reward than thousands and thousands of honest laborers do collectively during the same period of time. Nor does he run as great risks to life and limb as the average laborer who is employed in mechanical pursuits. A single mine explosion destroys more lives, injures and cripples more men than are executed by law, or injured in the pursuit of criminal occupations in half a century. The average professional thief gets more comfort and luxury and loses less time from his vocation than the average laborer.

That both moral persuasion and punishment have given but little result in the suppression of crime in times past must be admitted. The proportion of crimes to the population has varied comparatively little in the remote past. Statistics tend to show at the present time that crime is increasing. According to a report made at a recent meeting of the Medico-Legal Society of Chicago, a comparison of the census of 1850 with the census of 1890, shows that the population has increased 170 per cent., while the proportion of criminals has increased 445 per cent.

Preaching, while all well enough in its way, has accomplished even less than punishment. This is especially true with the criminal of the habitual type. I do not claim that this failure is due to the intrinsic fallaciousness of moral methods of persuasion, but the individual with a degenerate brain, who is possessed of absolutely no capacity for moral impressions, is poor material upon which to work. As outlined in the report to the Medico-Legal Society already alluded to, the habitual criminal is an abnormal man; this abnormality manifesting itself (1) physically by stigmata in cranial and cerebral development; by criminal physiognomy; by anomalies in the muscular, respiratory, and circulatory systems; by anomalies

in motor activity, and in physical sensibility; and (2) psychically, by moral insensibility; by a lack of forethought, by a low grade of intelligence; by vanity; by emotional instability, and by slang (thieves' jargon).

In the consideration of such a vital question as the management of the criminal class, the sentimentalist and his natural ally, the preacher, have joined hands on the question, and to them the world has looked for the reformation for which it has waited in vain. Such practical treatment as the question has received has been chiefly in the direction of devising ways and means to punish the criminal, the building of penal institutions and scaffolds, with the expensive law machinery which leads thereto. And then society has set about devising ways and means to save the elect from its own laws, and has split hairs to such an exceeding degree of fineness that there lies between the thieving corporation or the absconding millionaire, and the petit larceny fellow, who steals to live, an impassable gulf, one at least, across which Mammon alone can build a bridge.

Society makes crime; manufactures its own criminals, and winks at the violation of its own laws in high places. It gives the criminal all facilities; the best of inducements for carrying on his avocation, and then threatens to punish him if he follows the path cut out for him. Above all, society gives the criminal a chance to breed. Crime, as I have said, seems to be more profitable, safe, and comfortable on the average, than honest labor. What have our preachers, moralists, sentimentalists, and law-makers accomplished? They have spent the energy and money of the people for nothing. Every penal institution, every expensive process of criminal law, is a monument to the stupidity and wastefulness of society—an expenditure of money and energy to cure a disease which might be largely prevented. We have millions for courts of law and penal institutions, but nothing for the salvation of the children of to-day, who will be the criminals of the future. The first and worst injury that society inflicts upon the criminal is, allowing him to be born. The criminal has a good and just cause against us.

The principal remedy for the conditions which tend to manufacture criminals out of young children, consists in making them wards of the State, where it shall be shown that their parents are unable or unwilling to care for and educate them properly, or where it shall be shown that the children are vicious, either personally or in association, and above all, in cases in which the children are of criminal parentage. *The management of these children should begin before they commit criminal acts.* They should be taken charge of and placed in suitable institutions in which physical, as well as intellectual and moral training are followed. The first duty of the State to the degenerate, is to make him a healthy individual and give him the physical capacity necessary to enable him to become a useful citizen. If the child is exposed to evil influences and sources of corruption, it is the fault of our social system, and one which should be corrected. Good morals should not be expected from diseased children. The moral sense is the product of a healthy brain, and to be health the brain must be fed with good blood, a condition which is not possible in the case of the young waifs or neglected children whom we see about our streets. That physical and moral training is beneficial, is shown by the records of the Elmira State Reformatory, the results of which have been phenomenal. If so much can be accomplished in such an institution, which is distinctly reformatory and to which children are only sent *after* they become offenders against the law, how much more effective might the same system be, if used as a method of prevention in the case of children who have not yet become criminals?

The adult criminal must be separately considered. He is thoroughly developed in his criminal propensities; his organization, such as it is, is complete, and in by far the larger proportion of instances it is impossible to bring about moral reformation in him. Punishment rarely cures; there must be some radical fault in the system, else we would not obtain such meagre results.

Criminals should be confined to institutions in which proper physical and intellectual training are brought to bear, and in by far the smaller proportion of cases excellent results may be obtained, and when it is believed that a cure of criminal propensities in this relatively smaller number of criminals has been brought about, they should be released upon parole, but should still remain the wards of the State for a certain length of time. The duration of sentences should depend mainly upon the question of cure rather than upon the enormity of the original offence, the exception to this being certain cases of murder and the crime of rape.

Habitual criminals, certain murderers, and rapists, should be emasculated. This serves three purposes: (1) The rational punishment of the individual. (2) A powerful moral influence upon

other and prospective criminals. (3) The criminal is prevented from perpetuating his kind.

Something like twenty-five years ago Dr. Gideon Lincecum of Texas, a very able physician and a scientist known all over the world, appeared before the Texas Legislature and ably advocated the substitution of castration of criminals for capital punishment. The result was that he was set down as a crank, while a howl of derision and disapprobation arose all over the land. By some this general protest was accepted as an argument —however, like all of the subsequent objections which have been advanced, it was based entirely upon sentiment. Dr. Lincecum's plan is now being advocated in many quarters, not as a substitute for capital punishment alone, but as a method applicable particularly to habitual criminals and rapists. Most of the opposition which is now being exhibited toward the plan is of a sentimental nature. As an illustration of this sentiment, a recent address upon the subject before the Medico-Legal Society of Chicago by a prominent practitioner of law in this city, was excellent. Natural as sentiment may be in certain quarters, it is remarkable that a practitioner of law, and a man of standing in his profession, should come before an enlightened medico-legal body and protest against what would inevitably be a great step in sociological progress, and protest upon sentimental grounds. I do not oppose sentiment in general, but sentiment applied to sociological problems is—well, it should be a back number; it certainly is misplaced.

There is one feature of castration which makes it far superior to capital punishment in most cases. Executions do not punish, and are but an evanescent lesson to others. A few castrated murderers, habitual criminals, and rapists scattered throughout the community, would be most efficient aids to the criminal memory.

Oliver Wendell Holmes once said: "If you want to reform a man, begin with his grandfather." I offer as an amendment that if you want to reform the criminal, castrate both his grandfather and grandmother. There is but one substitute: Take the children of to-day, who will be the grandfathers of future generations and make useful citizens of them. And yet, this failing, asexualization comes into play.

A legal gentleman who spoke in opposition to the proposed method before the Medico-Legal Society of Chicago referred to the viciousness and savagery of the eunuch of the East as an illustration of the danger of castration. Before he makes any deductions from the characteristics of the eunuch, he must compare him with the race from which the eunuch sprang. I presume that castrating the "Ahkoond of Swat" would not have produced a nineteenth century dude. The Oriental eunuch comes from a race of savages. The Amazons of Dahomey are not only savages, but after being made practically neuters, are trained by savages for savage deeds. Another point: they are castrated young and trained afterward. We are advocating the castration of the adult criminal only. The result will not be the development of savage instincts in the criminal, but if the experience of countless generations goes for anything, the operation will be likely to tone him down to a marked degree. That this gentleman was absolutely wrong is shown by observations of animals and by thousands of cases of castration in the human subject. The emasculated choir-boys of Rome did not develop bloodthirsty instincts. There is not a practising physician who does not know of dozens of women who have been asexualized for the relief of ovarian disease, yet where is our Amazonian army?

In conclusion, I desire to say that the advocates of castration demand it—not for all criminals, but for habitual and incurable types, for rapists, and possibly for some murderers. As far as the latter are concerned, their execution is useless. Let them choose between scientific experimentation under anesthesia, and castration. They might expiate their crimes by benefiting scientific medicine. As for capital punishment, away with it!

With regard to sexual crimes, asexualization is of very practical importance to the people of the South, among whom such crimes, particularly on part of the ignorant Southern negro, is of especial frequency. This was one of the important points brought out by the discussion before the Medico-Legal Society. It is to be understood, however, that the discussion of this subject applies to all sexual criminals of whatever color; the negro criminal of the South is especially considered, because he has been very prominent, not only with reference to the frequency of the crimes which he has committed in this direction, but because of the barbaric treatment which he has received in certain communities as a method of punishment. In response to a request made by my friend, Dr. Hunter McGuire of Richmond, Va., I made an exhaustive discussion of this subject several years ago in a paper which I then published. I called attention to the futility of lynching and legal executions or imprisonment.

Nowhere in the history of civilization has the futility and barbarity of capital punishment been

so well shown as in the punishment of negro rapists in the South. The negroes who perform the acts under consideration are the lowest and most ignorant of the race. They cannot read the newspapers, and it is conceivable that a negro may be hanged or burned at the stake without the negroes of the adjoining county becoming apprised of it. The lower-class negro is subject to attacks of *furore sexualis*, which completely remove any inhibitory impressions which he may have received, even though in his rational moments he knows that swift and terrible vengeance will be meted out to him for the crime of rape. He is usually a religious fanatic who sees the gates of Heaven yawning wide to receive him just beyond the scaffold. Those gates are ever hungry for the fruit of the gallows-tree, and your negro fanatic needs no priest or clergyman to bid him *bon voyage*. The Zulu crops out in his not very remote descendant on such occasions. Death is no punishment, and its moral effect is but transitory on those about him. What a rapist needs is an ever-present object lesson, and one which puts the criminal beyond the power of further criminal acts of like nature.

A negro clergyman of education, in commenting on my paper on this subject, said: "The conceded superiority of the white race has much to do with rapes committed on white women by the negro. Art, literature, and religion combine to inflame the passion of the negro for white women. Your fairies, nymphs, goddesses, and angels are all white. Did you ever hear of a black angel? The result is an inflamed passion and an exaggerated curiosity on the part of the negro."

It is my opinion that a few castrated negroes scattered throughout the South would do more good than a multitude of executions. The colored clergyman whom I mentioned, suggested that the offender's ears should also be cropped, that he might be easily recognized.

I repeat, I do not indorse this method as applicable to the negro rapist alone, but to all criminals of that particular type.

In one of the papers read before the Medico-Legal Society mentioned, a distinguished student of the subject became a trifle sentimental over the case of a boy of seventeen years of age, who was committed for killing a policeman—"his first killing." This boy behaved well for several years, and the author of the paper said "he was cured." Cured of what? He never *was* a professional murderer. His was a sporadic case of criminality and one in which it is impossible to say that the same conditions would not lead to another murder. No matter how well behaved, that boy was probably still dangerous. From an extensive experience, I am free to say that convicts doing time for murder are nearly always well behaved. First, because their crimes were committed in most cases under exceptional conditions of excitement. Second, good behavior affords the only hope of men who are not imprisoned for a definite term, but who may at some time excite the pardoning sentiment in somebody or other. Beware of well-behaved murderers unless there be something more than good behavior as an evidence of cure. Repentance is, of course, no evidence—they are nearly *all* repentant. Understand, I believe that quite a large proportion of murderers might be liberated without danger, but I simply desire to call attention to the difficulty of deciding this point. Your sporadic murderer may be "cured" until such time as certain sources of excitement control him. *He is much more difficult of analysis than the habitual criminal.*

The author of the paper to which I allude also suggested a board of medical examiners to diagnose the grades of criminality and decided upon appropriate measures of treatment. Now, this is all very well in theory, but will it work? Who shall form the board, how shall they be appointed, and upon what absolute data shall they form a diagnosis? I firmly believe that the existence of such a board for six months would, with the meagre data at our command, bury the science of criminal anthropology so deep that it could never be resurrected. Let us rather bear those laws we have than fly to boards we know not of,—that would make confusion worse confounded. No, a board of diagnosis of crime would be a dangerous thing. Let us concern ourselves with the conditions that produce the criminal and the best means of cure.

It has seemed to me that we are working at a disadvantage by considering the criminal of to-day as being the most important factor in the crime problem. I repeat—Dr. Oliver Wendell Holmes voiced the central idea when he advised us to reform a man by beginning with his grandfather.

The repression of the criminal class is a question which should be dealt with from a practical standpoint. Sentiment, if exhibited at all, should be in behalf of honest people, not the criminal. The maudlin sentiment which impels fashionable women to present bouquets and frosted cakes to imprisoned criminals may yield to the pressure of the new method of criminal correction. Like all

other diseases the disease of crime is one which is more rationally treated by prevention than by curative methods. Will not the law-maker join hands with the medical practitioner and endeavor, even at the sacrifice of his own interests, to prevent the diseases which he treats?

BRAND TREATMENT OF TYPHOID FEVER.

By ARTHUR J. PATEK, A.B., M.D.,
OF MILWAUKEE, WIS.

In an article entitled "Hydrotherapy in Typhoid Fever," that appeared in the Medical News of February 8th, Dr. A. L. Benedict, of Buffalo, casts such discredit upon the efficiency of the Brand Treatment, as it is systematically employed at the present time in all modern hospitals, that I beg permission to say a few words in its defense. I would not have it understood that this treatment is but a theory still groping about for advocates and defenders. It has enough able supporters. And it is my desire merely to refute some misleading statements and arguments made by Dr. Benedict, which unanswered, would be prejudicial to the best interests of the method. I shall also take this opportunity and privilege to elucidate a few points in regard to the Brand treatment—based upon facts, not upon theories.

If the writer had studied carefully the reports of Dr. Baruch, those recently published by Professor Osler in the Johns Hopkins' Hospital Reports, and the annual records of typhoid fever cases occurring at the German Hospital of Philadelphia since 1890, and a more recent record of such cases at the Pennsylvania Hospital, reported in the Medical News by Professor J. C. Wilson, some of his statements of condemnation would not have been made. Since Dr. Benedict has based his conclusions wholly upon theoretical grounds and argues from analogy only, it is but fair that a word should be spoken, based upon a foundation of facts without the fallacious use of analogy, in support of the argument. I will, therefore, confine myself to facts as they have been elicited by observation.

Like Dr. Benedict, it has also been my good fortune to frequently watch others of both sexes and all ages enjoying the sport of bathing and swimming at bath establishments and watering places, and I must say that it is my impression that exactly those youngsters who went in swimming, twice or even thrice daily, for the love of this sport and not because a cruel doctor had so ordered, were the hardiest of boys, and that this excess did not result in "diminished strength, lagging at games, and other athletic exercises, loss of appetite, predisposition to cold, transient dyspepsia," etc. I too have often noticed boys with "livid or almost white lips" and boys whose lips and skin were purplish-blue after coming from an open-air bath, but can also recall that these were the boys who were the most inactive while in the water and were content to stand shivering, with arms folded, in water waist-deep, and watch their more lively companions sport about, keeping up a good skin circulation and "working up an appetite." These latter went into the sport for all it was worth—and it was worth a great deal to them—and they came from the bath with a ruddy, glowing skin; the former went in swimming merely to join their fellows, and they are the ones who emerged from the bath with livid or blue lips.

It is quite evident that Dr. Benedict is judging, as I think fallaciously, from observations made upon the supposedly healthy, and not from any experience he may have had with typhoid fever patients, and is placing these *a priori* arguments to the credit or discredit of diseased states.

There are two points upon which Dr. B., who has evidently not had the privilege of coming in direct contact with typhoid patients, before, during, and after immersion treatment, needs information. Firstly, the technic of the bath procedure. Secondly, the effects of such treatment, from which latter we shall deduce the indications for its application.

As to the technic, I may state that the patient, while in the bath, is never for a moment supposed to be lying in the cold water, an inactive, shivering, helpless mass of humanity. Far from it: he is encouraged to rub himself and an attendant also applies friction, and thus superficial circulation is kept up, there is not the danger of internal congestion, and the patient emerges from the bath, not blue, but red as to his skin. The whisky before or during and after the bath is a very necessary adjunct to the treatment.

Now, let us see how the patient's condition in the bath differs from that before immersion. He may have been somnolent and delirious; now he opens his eyes, seems to recognize his surroundings and may even answer questions rationally. His respirations may have been shallow and frequent; now he breathes more deeply, hence more efficiently, and less frequently. His pulse may have been feeble and have registered 140 beats per minute; now it is more forcible and registers 110 or less.

What are the very evident deductions from these facts? (That they are facts anyone can satisfy

himself by a visit to a hospital in which this treatment is used). We must conclude that the bath fulfils several indications, and although Drs. Wilson, Osler, and others have at different times endeavored to emphasize that its antipyretic action is of the least importance, yet physicians are continually falling into the error of classing the cold bath as synonymous with antipyrin and quinin. The indications to be fulfilled are : stimulation of superficial circulation and cutaneous excretion, stimulation of general circulation and respiration, sedative action upon the nervous system, and lastly, reduction of temperature. I would not be considered going so far as to say that the happy results cited always attend the cold bath, though sufficiently often to impress an observer forcibly. And I would beg Dr. Benedict to read carefully not only the statistics of Drs. Wilson and Osler, but also the text in which these records are very thoroughly explained and in which contra-indications to bathing are mentioned.

Osler, in the Medical News of October 12, 1895, says: "Two advantages are claimed for hydrotherapy in typhoid fever; a mitigation of the general symptoms of the disease and a reduction in the mortality. Our experience during the past five years bears out these claims." And again: "As has been urged so often and so ably by many writers, the beneficial action is not so much special and antipyretic as general tonic and roborant."

In conclusion let me summarize by a refutation of several of Dr. Benedict's propositions:

Proposition 1. That "immersion rarely fulfils the requirement of an antipyretic, producing the least shock," etc., is quite as untrue to fact as

Prop. 2. That "occasionally an antipyretic drug, such as acetanilid, phenacetin, phenocol, or lactophenin may be used" is dangerous in practice.

Prop. 4. "The blood is thrown inward to organs already infiltrated," etc., and

Prop. 6. "The immediate effect of cool immersion is to cause congestion of the internal organs." Hypostatic pneumonia and other internal congestions are rarely encountered when patient is subjected to systematic, properly conducted bathing. The establishment of a good superficial circulation militates against this danger.

Prop. 14. That "the typhoid patient has not the benefit of exercise during or after the bath nor of increased circulation and respiration inevitable in the effort to keep the nose above the surface of the water" is not in accordance with facts, as is explained above.

Prop. 15. "The typhoid patient, if immersed at all, must be lifted to and from the bath with the greatest care," etc. This is done in all well-conducted hospitals.

Prop. 17. "In a comparison of death rates the advocates of immersion very properly exclude fulminating and neglected cases from their own tables," etc. This is certainly a perversion of facts, as a glance at the tables of Wilson and Osler will show. The percentages are drawn from all cases treated and these are then further analyzed.

Prop. 23. "We may well doubt the good faith of some who practice immersion in hospitals but who do not urge it on their private patients," etc. It is impossible to overcome sentiment. Does it follow that the inunction treatment of syphilis, which is now universally conceded to be the most efficacious, but can rarely be applied in private practice, is by reason of this the less worthy of good faith ? The Brand Treatment is no longer a theory, nor are its advocates clamoring for the recognition or introduction of an experiment. They are dealing with facts.

Those who study carefully the rules laid down for the application of the Brand treatment and take the trouble to follow the well-tabulated records of careful, conscientious men, will surely be convinced that the immersion treatment of typhoid fever has a *raison d'être*, and that, in taking in good faith what is claimed by these men, they will be following, not a blind trail, but a path well-paved by keen observation and mature judgment.

CLINICAL LECTURE.

RETINITIS AND CHOROIDITIS.[1]

By L. WEBSTER FOX, M.D.,
OF PHILADELPHIA;
PROFESSOR OF OPHTHALMOLOGY IN THE MEDICO-CHIRURGICAL COLLEGE.

Gentlemen: I wish to recapitulate part of our lecture of last week in which I called your attention to the differential diagnosis between retinitis and choroiditis. You were told that retinitis seldom occurred idiopathically but was usually the result of some constitutional disturbance, and at the head of these disturbances syphilis heads the list. I called your attention to the fact that in all cases where you do not have a specific history and where the vision has fallen below the normal and the ophthalmoscope fails to show you any pathological change in the retina, you should always test the urine for albumen.

So as not to mislead you relative to the frequency of retinitis following syphilis or albuminuria, I might say that in syphilitic retinitis we usually have other tissues like the uveal tract, choroid, and ciliary bodies and iris com-

[1] Delivered at the Medico-Chirurgical Hospital, February 28, 1896.

plicated, whereas, in retinitis, due to albuminuria, we have the retina alone affected. I wish to repeat that we also have functional disturbances which do not always correspond to the ophthalmoscopic signs. You may remember the patient whom I brought before you early in the session. This patient has suffered the most intense agony from retinitis, yet the ophthalmoscope reveals nothing. In spite of the most active treatment, both externally and internally, she is still blind, although no change in the tissues of eyeballs are apparent.

Then again we have various forms of retinitis, such as the toxic amblyopias, in which vision is seriously interfered with and no morbid changes occur in the retina. In these cases there is no pain whatsoever. I have had several cases wherein young children varying from the ages of eight to fourteen the vision has fallen to $\frac{1}{200}$ and the visual fields contracted to ten degrees. This form of retinitis is extremely rare and is evidently associated with a lowering of the nervous system. Under the active use of the constant current the vision has returned to normal in a very few weeks. In these cases the ophthalmoscope shows no change in the fundus oculi, and the amblyopia is not due to toxic influences because these patients were children and hence were not addicted to drugs of any kind. The most important form of retinitis which interests the general practitioner is that caused by Bright's disease. The eyelids are to him as characteristic as the fan-shaped white spots to the ophthalmologist.

Edema of the lower eyelid is a very characteristic symptom of Bright's disease. Associated with this puffiness of the eyelids we find the muscle of accommodation giving way. This condition shows more with hyperopes, suffering from retinitis than myopes. It is a singular fact that in certain forms of retinitis, both in the hemorrhagic and colloid variety, we fail to detect albumin in the urine. From observations which I have made, but have not been able to confirm, I feel that in certain forms of retinal hemorrhage, especially in the striated variety, we have the forerunner of non-albuminuric Bright's disease. Then again, we have the typical colloid deposits in the retina, vision fallen off to $\frac{10}{200}$, or even less. These white spots, sometimes as small as a pin head, or as large as a canary seed, are grouped together fan-shaped or like a sunburst. Even with such a picture you may fail to confirm albuminuria. Many of you will recall such a case, a young woman who came to the eye department some months ago for loss of vision in one eye. The ophthalmoscope revealed the picture, as shown to you on this painting, of a so-called case of albuminuria retinitis. To the students who were present at the examination I stated that the case was one of undoubted Bright's disease, and that the urine would show albumin in large quantities. Strange to tell you, the examination did not confirm what I had predicted. No albumin was found at this or subsequent examinations. The patient came under the care of Dr. S. Solis Cohen, to whom I sent a report of the ophthalmoscopic examination. Dr. Cohen could not detect any abnormal secretions in the kidneys during the time the patient was under his care. A week ago I examined the eye-ground again, and all traces of the retinitis had disappeared and the vision had returned to the normal. I believe, with Mohomed, that we have a functional stage of Bright's disease, and that it shows itself first in the retina, as a retinitis, high arterial tension, and when this condition exists for a longer or shorter period we have the colloid deposit, or even the retinal hemorrhages, and after this the change in the kidneys.

While on this topic of retinal deposit I must call your attention to the fact that in diabetes mellitus, which is a rare complication, we have a similar deposit in the retina, and it is almost impossible to detect one from the other by means of the ophthalmoscope alone.

This young woman, whom I present to you to-day, has a form of retinitis entirely unlike that about which I have just spoken. In examining her eyes externally you see nothing the matter; good movement, good color, bright and clear. She is, however, practically blind. She can walk about the arena fairly well. Upon testing her distant and near vision she was about one-fifth the normal, but when we test her visual fields they are contracted to almost nothing. As she expressed it, apparently her "eyeballs have grown very small, or as if she had two long tubes placed before her eyes, and as long as she looks straight ahead she can get along." In examining both eyes with the ophthalmoscope, we find the back of the eye covered with a deposit of black pigment, very marked in the periphery, less so at the equator, and little or none about the macula. It is exactly like this drawing, a picture not easily to be confounded with other deposits in the fundus. These masses of brownish pigment are very similar to the lacunæ and canaliculi of bone. At the periphery the deposit is *en masse*, while in the central portion of the eye-ground we have isolated plaques. One very characteristic point in this deposit is that it surrounds the blood vessels like moss about the branches of trees, and finally these blood-vessels become so contracted that they are scarcely visible. I have not seen this deposit earlier than the eighteenth year. In this patient there is contraction of the visual fields. As the patient advances in age the deposit increases, and as it does the visual fields grow less and the nyctalopia grows worse; ultimately blindness follows.

The woman before you is forty-two, and if we could get an accurate history, I am sure that her defect of vision would date back to about her twentieth year.

As to the cause of this disease, heredity has a great influence, and I believe that consanguineous marriages are responsible for this evil more than we like to admit. As the result of an intermarriage of first cousins I had under observations fifteen descendants suffering from retinitis pigmentosa.

As regards the treatment I am convinced that the constant current is the only means at our disposal which amounts to anything. It must be kept up for years. It seems to prevent progression, and in some cases I have seen marked improvement in the visual fields and central acuity. The cases under thirty years of age respond more promptly than those of maturer age. This patient has had daily treatment under the care of Professor Burr. She shows evidence of an appreciable improvement.

She, however, is unable to remain in the hospital any longer, and therefore will pass away from our care and her fate may be easily forecast.

The choroid, consisting of six layers, is second in importance of the coats of the eye. It is the blood-carrying coat, and from its pigmentation plays a very important rôle in the protection and aid to our vision. When the pigment is entirely absent, as in the case in albinos, there is great difficulty in seeing.

This coat, or uveal tract, as it is also called, is very prone to localized or general inflammation. It may be serous, plastic, or purulent. The symptoms in serous choroiditis are not well marked. The ophthalmoscope shows a turbid condition of the vitreous lying close to the retina with foci of exudation here and there over the choroid. In this stage of the disease it is very difficult to differentiate between retinitis and choroiditis. The vision is clouded and may remain so during the inflammatory stage. A patient will frequently complain of phosphenes, and spots before his eyes, during this stage. If we have large areas of exudations and they become absorbed, we have very defective vision, and here or there in the visual field scotomata, or blind spots. The choroid coat has a moth-eaten appearance.

We recently followed a case like this: A woman referred to the clinic by Dr. W. S. Stewart, who had a marked case of serious choroiditis. There was a history of sudden dimness of vision in the left eye. I examined the patient very carefully and could only find an area of haziness in the posterior part of the vitreous chamber. Some of you who were present at the examination may remember the patient. At the end of forty-eight hours the haziness had not increased but a focus of exudation was seen just below, and about the size of the optic nerve. This condition was about the same for two weeks when this island of deposit began making its appearance, which grew darker and darker until it became black. In five weeks this spot of choroiditis had the appearance of being there for years.

The case that I have described is, I believe, the most common variety and causes the atrophic spots so characteristic of choroiditis as we see them with the ophthalmoscope.

Plastic choroiditis is very serious in its outcome. Beginning with a sudden dimness of vision, throwing out deposits of lymph, breaking down of tissue until the eyesight is gone, and the ultimate softening of the eyeball. Fortunately, these cases are not very common. Between this disease and purulent choroiditis there is very little difference. In the latter disease the conjunctiva and subconjunctival tissues are densely infiltrated with serum. There is great pain, and the eyeball fills with pus and we have a case of panophthalmitis.

You have seen in the out-patient department quite a number of cases of disseminated choroiditis. Scattered over the fundus isolated spots, small in area, almost perfectly round, some few oval, white in the center and a reef of black pigment around them, is the picture which is so characteristic of the disease due to syphilis.

We have recently had quite a number of cases of choroiditis circinata, usually found in old people. I believe this is associated with senile degeneration and has no relationship with kidney changes.

The macula region is frequently the seat of an inflammation which shows itself in punctiform deposits but circumscribed and limited to this region. The vision is more or less affected in this form of disease.

Some years ago I had a patient in whom there was a sudden loss of vision of his visual center. Upon examination I found a small, brownish-red hemorrhage in the maculæ, both were perfectly circular and in due time became absorbed. This young man, who is living in the city, has had no further recurrence, but his central vision never became as acute as before the hemorrhage.

In progressive myopia we have more or less change taking place in the choroid. This becomes more marked about the optic nerve entrance than elsewhere, but sometimes this change takes place over the whole eye-ground as is demonstrated in the patient I now bring before you. He comes from the western part of the State, where, until recently, he has been attending a literary college. For years he has worn glasses, near-sighted ones. While his vision was never up to the standard, yet he was able to follow his work. Recently he lost the power of reading small type and his visual fields also became so limited that he is practically blind.

Upon examining him in the dark room I found most extensive spots of choroiditis, in fact, almost complete atrophy of the choroids. To those students who were present at this examination I called attention to the great changes which had been going on, also to the fact that the retina too was undergoing an atrophic change. The retinal blood-vessels were attenuated and passed over the white spots in the choroids. In quite a number of places the vessels were seen in the sclerotic coat.

The conditions here are most grave. Under the guidance of a skilful ophthalmic surgeon this young man should have been relegated to an out-door life and should not have been permitted to have studied from books. The prognosis is very unfavorable and the only hope that we can hold out toward aiding his vision, is preventing him from using his eyes for small type, living an outdoor life, and trying to stimulate the shreds of the choroid and retina still remaining by the constant current and such internal remedies as will preserve the normal tissue.

This case was one of progressive myopia in which the choroids became involved and blindness followed. As ophthalmic surgeons, such cases will come under your care, and you must always guard the patient from too much near work. If the progression is rapid you must make the patient leave off near work for several years. The younger the patient the more unfavorable will be the ultimate outcome.

The general treatment in cases of choroiditis must be towards the dyscrasia, and when errors of refraction exist you must correct them, and urge upon your patients the necessity of frequent examinations both with the ophthalmoscope and for new glasses.

CLINICAL MEMORANDA.

VERTIGO OF NASO-PHARYNGEAL ORIGIN.[1]

By W. SCHEPPEGRELL, A.M., M.D.,
OF NEW ORLEANS, LA.;

REFLEX disturbances due to pathological conditions in the nose have been frequently reported, but the naso-pharynx, except in cases of hypertrophy of the pharyngeal tonsil, has not often been found to be an etiological factor in reflex disturbances.

Vertigo of laryngeal origin is sometimes met with in practice and I have had occasion to see several cases of this interesting form of neurosis. Headaches are occasionally due to a catarrhal condition of the post-nasal cavity, but the following case, in which vertigo was induced by a retro-nasal catarrh, is certainly a rare instance in rhinological literature.

On May 13, 1895, Frank S., age twenty-four years, was referred to me by Dr. John B. Elliott; he gave the following history:

For several years past he has suffered from "catarrh," but for the last two years, while making an attempt to clear his throat (naso-pharynx) after breakfast, he gags and becomes dizzy and has to take hold of a chair or other article to prevent himself from falling. The vertigo is sometimes very severe, and on two occasions he completely lost consciousness. The first time this occurred he was in his room and, while making an effort to clear the naso-pharynx of secretion, he fell and remained unconscious until his relatives, who heard the noise of his fall, came to his room, a period of probably two or three minutes. On the second occasion he fell in the street and did not recover consciousness until he had been assisted to his feet by some passer-by.

Recently he has also had great pain over his right eye, for which a physician had prescribed phenacetin, and the patient has acquired the habit of taking this now in large doses. One physician whom he consulted treated him for urethral stricture without, however, any improvement of his symptoms. He then called on Professor Elliott, who at once recognizing that the symptoms were due to some pathological condition in the nose or throat, referred the patient to me.

A rhinoscopic examination showed a cartilaginous thickening of the septum into the right nostril and a hypertrophy of mucous membrane, causing marked stenosis of this passage. The naso-pharynx was in a state of chronic inflammation and covered with a thick secretion, due to the defective respiratory function of the nose.

With a view of improving the nasal respiration and to prevent the occlusion of the opening into the right frontal sinus, which was evidently the cause of the pain in the supra-orbital region, the septal thickening was removed and the hypertrophic condition of the mucous membrane reduced by the electro-cautery; an alkaline wash was prescribed so that the patient could cleanse the nostril and naso-pharynx.

The patient began to improve as soon as the treatment was well advanced. The pain over the eye ceased, and with the improvement in the nasal respiration the naso-pharyngeal irritation disappeared. Eight months afterwards the patient reported that he had had no recurrence of either the vertigo or the pain.

EXAMINING RECTAL MUCUS FOR TUBERCLE BACILLI, A USEFUL DIAGNOSTIC PROCEDURE.

By JOHN P. SAWYER, A.M., M.D.,
OF CLEVELAND, O.;
PROFESSOR OF MEDICINE AND CLINICAL MEDICINE, WESTERN RESERVE UNIVERSITY; VISITING PHYSICIAN TO ST. VINCENT'S CHARITY HOSPITAL.

CASES are continually occurring in which we suspect the existence of incipient phthisis, but in which, owing to utter absence of expectoration or to absence of *bacilli tuberculosis* in the sputum obtained, we are unable to demonstrate the correctness of our suspicions by ordinary routine measures.

This is notably true in primary renal and intestinal tubercular lesions. Examination of urine and of feces is of great assistance, but the search for bacilli in the stools is beset by obvious special difficulties, which prevent the routine examination in these suspected cases. The difficulty is all the more deplorable because there is reason to think that the intestinal route of infection is more common than has been generally supposed. Few observers now neglect to examine the secretion of *fistula-in-ano* or of ulcerations of the rectum.

It is not a far-fetched idea to make, in the cases suspected as above, an attempt to find whether or not the tubercle bacillus be present in the rectal mucus in numbers sufficient to be of diagnostic import. The finding of an occasional *bacillus tuberculosis* in the stool is held to be due probably to ingestion with food or drink or saliva; but the finding of clusters of these bacilli, particularly on the surface of formed stools, is of diagnostic significance, and can be relied upon to indicate tuberculous processes in the intestine, probably in the neighborhood of the ileo-cecal valve. With this in view, it is easy to see that in the passage of the formed stool through the sphincter, the mucus, in which are carried the bacilli from a locality higher up in the intestine, is partially held back, retaining here the sign of the destruction above, as well as the seed of fresh processes, whose later occurrence renders clear the existence of a condition suspected before, but now already well advanced.

In my service at Charity Hospital, during the past few months in three cases as above, the *bacillus tuberculosis* was found in the rectal mucus in considerable numbers when wholly absent in sputum, or when no sputum could be obtained, no local lesion being present to account for, or call attention to, tuberculous process at the anus. The mucus is obtained, after placing the patient in position to examine for piles and directing him to bear down as though at stool, by gently removing a little mucus from the everted membrane with a sterile loop and spreading it upon a clean cover-glass, to be treated exactly as sputum in

the ordinary examination. The use of a rectal speculum, while perhaps advantageous, has not been necessary.

Pending the results of farther trial in my own clinical material, and of control experiments, I present this note, with considerable confidence that others trying this procedure will find it an aid to early diagnosis in a class of cases where all hope of therapeutic efficiency lies in prompt recognition.

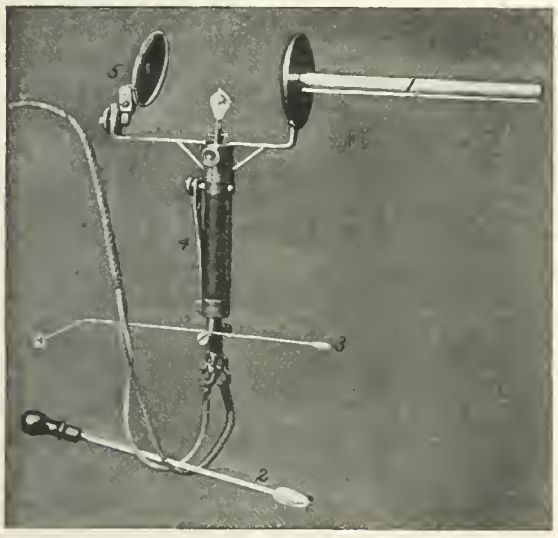
NEW APPARATUS.

A NEW URETHROSCOPE.

By JOHN A. HAWKINS, M.D.
OF PITTSBURG, PA.

THE instrument here shown is the result of numerous experiments on the part of the writer in this line and has given him more satisfaction than any other instrument tried. It has been in use for more than a year.

Up to the present time Leiter's instrument has had the preference and during its time served its purpose, but is very heavy and unwieldy. Another objection to it is that as the line of vision is over the top of the mirror, little more than one-half of the light thrown in the direction of the mirror can be utilized, owing to the removal of a segment of the mirror to complete the axis of vision.



HAWKINS' URETHROSCOPE.

Dr. Otis attempted to overcome this difficulty by devising his "Perfected" urethroscope, which consisted of a T-shaped tube, in the vertical portion of which was inclosed an incandescent electric lamp, whose rays were concentrated by a small "bulls-eye," placed in one end of the horizontal portion, and which was inserted through a Klotz tube. The objection I have found to this instrument is that as it is necessary to look over the condenser in using the instrument, the rays of light are not thrown directly down the tube but are thrown obliquely and the illumination is not only poor but the image is not properly defined.

The principle of the instrument here shown is that of the ophthalmoscope and consists of a Klotz endoscopic tube to which is attached by clamp a U-shaped bar. At the opposite end of the bar is placed an adjustable mirror, through the center of which is a perforation, as in the ophthalmoscope. This mirror is set in a ball-and-socket joint and is adjustable in all directions. It is also movable, either up and down or to and from the lamp. The source of light is from a small incandescent lamp, located at the top of the hand-piece, the hand-piece being movable in a vertical position in a tube on the U-shaped bar. A thumb-switch, commensurate to the requirements, is placed nearest the operator.

Completed, the instrument weighs but two ounces, and if made of aluminum, would weigh but a small fraction of an ounce.

The advantages I claim over the older instruments are: it is lighter and can therefore be handled with a more delicate touch. All the light thrown in the direction of the mirror is utilized, as all parts of the mirror are reflecting the light directly down the tube, while the operator's eye is in an optical axis with the object. There is plenty of room for the operator to make applications to the diseased mucosa. All Klotz' tubes are easily attached to the instruments, as with other instruments. The illustration in itself fully explains the appearance of the urethroscope. There is no reason why this same instrument is not applicable to the examination of the ear or other cavities if provided with proper specula.

MEDICAL PROGRESS.

Extra-peritoneal Uretero-Cystostomy, with the Formation of an Oblique Canal.—To obviate the dangers that attend the establishment of an artifical communication between the ureters and the bladder through the peritoneal cavity; in the correction of such conditions as uretero-vaginal fistula, WITZEL (*Centralblatt für Gynakologie*, 1896, No. 11, p. 289) proposes to detach the peritoneum and draw the fundus of the bladder toward the ureter, which is made to enter the bladder obliquely, as it normally does. In the case of a twenty-year old woman, with a uretero-vaginal fistula, in whom other measures had failed, this procedure was successfully carried out. After a median abdominal incision had been made, the posterior layer of the peritoneum was incised in the neighborhood of the divison of the iliac artery and the thickened ureter found. Through an incision at about the middle of the broad ligament the lower extremity of the ureter was found and divided between two ligatures. The distal extremity was then closed by sutures and dropped into the pelvis. By means of a long pair of forceps, introduced beneath the peritoneum on the side of the bladder above the innominate line and over the iliac fossa, the proximal extremity was drawn down. The wounds in the peritoneum, including the median one, were closed and the subsequent procedures conducted outside the peritoneum.

The bladder was now readily drawn to the middle of the iliac fossa, covering the exposed extremity of the ureter to the extent of an inch and a half, and fixed in this situation by means of several strong catgut sutures. Opposite the obliquely divided extremity of the catheter a small opening was made into the bladder, and the mucous lining of both was united by a ring-suture of fine catgut. Another series of sutures united the remainder of the walls. Parallel with and on either side of the ureter the wall of the bladder was elevated into folds, which were united by sutures, so as to surround the ureter for a distance of about an inch and a half. An additional opening was made in the abdominal wall for the introduction of a glass drainage-tube to the point of anastomosis, and the median wound was closed. A catheter remained in the bladder for four days. Union took place and function was restored without complication. A similar plan may be pursued in cases in which primary uretero-cystostomy is indicated.

The Transplanation of Tendons.—Franke (*Archiv für klinische Chirurgie*, B. lii, H. 1, p. 87) calls attention to the operation of Nioladoni for replacing the function of a paralyzed muscle by uniting the distal extremity of its divided tendon with the tendon of an unparalyzed muscle, and reports two cases and cites fifteen others in which this procedure proved efficacious. One of the cases was in a boy, six years old, who presented pes equino-varus as a result of a syphilitic encephalitis. After division of the tendo Achillis, the foot was strongly held in dorsal flexion and the tendon of the extensor longus digitorum severed, and its distal portion united by suture with the tendon of the tibialis anticus; the extremity being finally surrounded with a plaster dressing. The child, previously able to get about only with the aid of braces, was now able to run and play without artificial support. The second case was in a girl, five years old, who presented equino-varus as a result of an acute poliomyelitis early in life. An operation similar to that performed in the first case was done, with an equally satisfactory result.

Complete Resection of the Prostate for Malignant Disease.—Salitschew (*Vratch*, 1896, No. 2; *Presse Médicale*, 1896, No. 22, p. 131) has reported the case of a man, forty years old, who complained of intense pain referred to the rectum, and radiating toward the sacrum, the penis and the thighs, with hemorrhage from the bowel after each stool. On examination under anesthesia a diffuse tumor was found above the anus, and involving the rectum for a short distance. The overlying surface of bowel was ulcerated, especially in the region corresponding to the prostate. The seminal vesicles and the different canals were thickened and firm. In the depth of the ulceration, corresponding to the prostate, a catheter in the bladder could be easily felt. The glands of the pelvis, and of the inguinal regions, were not enlarged. A diagnosis of carcinoma of the rectum and prostate was made and confirmed by histologic examination. Accordingly, two-thirds of the rectum, the prostate, the lower portion of the seminal vesicles, and the adjacent lymphatic glands were removed. The superior third of the rectum was sutured to the posterior angle of the wound, a catheter fixed into the bladder, and the large opening packed with iodoform gauze. The wound slowly filled up and at the end of two months the catheter was removed, although a small fistula persisted. An ulcer formed over the sacrum and the patient died three and a half months after the operation. The *post-mortem* examination showed that death was due to a myelitis in a situation corresponding to the ulcer over the sacrum.

THERAPEUTIC NOTES.

Tannalbin is the name given by Gottlieb (*Deutsche medicinische Wochenschrift*, 1896, No. 11, p. 163) to an albuminate of tannin rendered insoluble in the gastric juices by being heated for five or six hours at a temperature of between 110° and 120°C., and yet slowly soluble in the alkaline intestinal secretions. The preparation appears as a pale-yellow powder, quite tasteless, and containing about fifty per cent. of tannic acid. Its clinical utility has been tested by v. Engel (*Ibid.*, p. 163) who employed it in forty cases of various forms of intestinal disturbance—catarrhal and diarrheal conditions—and found it to be an efficient intestinal astringent, possessing the usefulness of a tannic acid preparation without any ulterior influence upon the functions of the stomach. The drug was administered in powder form to adults in doses of 15 grains, and to children in doses of 7½ grains, three or four times a day, and preferably at intervals of an hour or two.

The Treatment of Symptoms following Oophorectomy.—The successful results obtained from the use of thyroid extract in the treatment of diseases dependent upon removal of the function of the thyroid gland has led Mainzer (*Deutsche medicinische Wochenschrift*, 1896, No. 12, p. 188) to employ a preparation of the ovaries of cows and calves in the treatment of the phenomena that often appear at the menopause, or in the sequence of removal of the ovaries for any purpose. In a given case the attendant symptoms, fulness of the head, palpitation of the heart, vertigo, flushing, and sweating, were relieved by the use of such a preparation, which was at the same time unattended with any unpleasant effect.

Hypodermic Injections of Iron for Grave Anemia.—In the treatment of grave anemia Menella (*Gaz. Herb. de Méd. et de Chir.*, 1896, No. 23) recommends the injection into the subcutaneous tissues of the gluteal region 15 minims of the first of the following solutions, followed at once by a like quantity of the second.

(1) Take of

Pure iodin	3 grains.
Potassium iodid	a sufficient quantity.
Distilled water	from 2½ to 5 fluidrams.

Mix.

(2) Take of

Iron and ammonium citrate	15 grains.
Distilled water	from 2½ to 5 fluid ounces.

Mix.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

SATURDAY, MAY 23, 1896.

THE SANITARY ADVANTAGES OF A GREATER NEW YORK.

WHATEVER argument may be made, on economic or political grounds, against the Consolidation Act creating a Greater New York, there can be no doubt that as a sanitary measure it is of immense importance to the people hereafter to reside within the district. It is a well-established principle that the health of several communities, occupying contiguous territory and constantly commingling in business and social relations, is best promoted and protected when it is under the jurisdiction of a single central sanitary authority. The drainage of unoccupied lands, the sewerage of built-up areas, the disposal of refuse, the supply and conservancy of potable waters, the housing of the people, are but few of the many questions that should be determined only after a comprehensive survey of the geological, geographical, and other conditions affecting the health of the people resident therein.

It is even more important for the protection of contiguous communities against contagious and infectious diseases that there be a central health authority which controls all the lines of communication along which the germs of disease can spread from one community to another. The appearance of smallpox in any village within the limits of the Greater New York is now a far greater menace to this city than would be an outbreak of that pestilence in New York itself. This is due to the imperfect methods of prevention and control of contagious diseases in rural communities as compared with large cities.

The economy of a single health administration over this district is an important consideration. A far less number of highly-salaried officials will be required in the new organization. The provisions which New York has already made for the care of contagious diseases, by the equipment of a steamboat service, and the erection of hospitals, will meet the requirements of the larger district with little additional expenditure of money. Our well-equipped disinfectant plant and laboratory can readily be made sufficiently complete to meet the demands of the increased service.

But we are not left to conjecture as to the sanitary advantages of the Greater New York. They have already been demonstrated in this very district, and within the memory of the present generation. In 1866 the Metropolitan Health Department was created, and its jurisdiction covered the territory embraced in the Greater New York measure. It was placed under the control of a Board of Health composed of members appointed from different sections of the district, with a central office in this city. Its expenditures were limited by the legislature to $100,000 per annum. The Board was scarcely organized when cholera, which had been making steady progress westward in Europe for a year or more, appeared at different points in the district. The public alarm was very great, for heretofore the pestilence had spread without hindrance from the inefficient methods adopted by our incompetent officials. But scarcely a week had passed when it was apparent that the scourge was under the most absolute control. The public excitement quickly subsided, few people left the city on account of cholera, and commerce and travel were scarcely interrupted. So promptly and thoroughly did the new Health Board deal with every case in the entire district, that in scarcely any instance did a

second case occur in the same family. All contagious diseases were promptly suppressed in cities and villages alike. Drainage of contiguous lands was effected on a large scale. In a word, during four years the initial sanitary works for the Greater New York were begun, and in some minor respects completed, and the people of the District are today enjoying their benefits.

The New Health Department should be organized in accordance with the latest and most approved teachings of sanitary science. It should be so constituted that only thoroughly trained sanitary officials can control its administration. On this account it is to be hoped that, in the appointment of the Commission required by the act, the Governor will select one member for his special knowledge of the organization of a Public Health Service.

PROGRESS IN MEDICINE.

A CRITICAL RESUME OF RECENT ADVANCE.

Two very radical methods of treating diseases of the heart have come into great prominence on the Continent and in England, but up to this time have never excited much attention or discussion on this side of the Atlantic. These methods are known as the Oertel system and the Schott system, both named in recognition of their practical discoverers and most able exponents. The latter, by virtue of its being less severe in its application and more plausible in its interpretation, has been embraced much more warmly than the former; and the literature and words of scientific commendation which are being published in support of it indicate that in the application of thermal, saline baths and of resistant exercises a most important measure in the treatment of chronic heart disease has been discovered. The scientific contributions which have been made to the subject in England and in Germany are already very numerous, but the physiological interpretation and the clinical application of the method have been much enhanced by several recent articles—one by Dr. R. F. C. Leech, of Edinburgh, another by Dr. Ernest Kingscote of Salisbury (*Lancet*, March 21 and 28, 1896), and a third by Dr. Robert Saundby of Birmingham (*British Medical Journal*, No. 1818).

The Schott method consists essentially of "exercises with resistance" and thermal baths containing carbonic acid gas and certain salts, in imitation of the Nauheim Springs. It is quite impossible in a brief reference to give a complete description of the technic of the method, but the agents brought into action by the bath are rest, temperature, water, salines, and carbonic acid. The rest is obtained by keeping the patient immersed in the bath, without moving, for a time varying from fifteen to twenty-five minutes. The temperature of the bath varies between 86° and 95° F. In the bath, to the special mechanical and physicial properties of the water, are therefore added those of temperature and rest. The saline bath and the carbonic acid bath both seem to have special properties and special influences upon the heart, the respiration, and the blood. It is not the action of any one of the agencies of the bath, but the combined effect, which is regarded by its advocates as curative. The temperature is considered one of the most important factors on account of its striking and far-reaching effects on the blood-vessels, and therefore on nutrition in general. It has been found that, although the temperature of the water of the bath is much lower than that of the body, the influence of the temperature is to cause definite dilatation in the cutaneous blood-vessels, and not a contraction, as one would theoretically suppose. The regular recurrence of these vascular changes brings about certain improvement in the nutrition of the tissues, which has a beneficial influence upon abnormal processes.

The resistant gymnastics, which consist of movements made by the patient against resistance, or, in some instances, of a graduated mountain-climbing, are considered of an importance inferior to the bath, yet the details of these resistant gymnastics are given most specifically, and are nineteen in number. They may be summarized, however, by saying that they consist of movements of the arms, hands, trunk, lower extremities, and feet in various natural positions against resistance made by the attendant. To overcome the resistance all the muscles are brought into moderate and increasing activity.

The cases which are particularly fitted for this mode of therapy are functional diseases, post-

influenzal conditions, nervous exhaustion, due to overstrain and mental worry, neurasthenia, particularly those of toxic and autotoxic origin, and *atonia* attending on anemia. Of the organic diseases, the valvular lesions of the heart, particularly those attended with hypertrophy and dilatation, seem to be benefited, and in many cases practically cured. The third class of cases in which it has been recommended includes simple angina pectoris and Graves' disease. The vast amount of evidence which has been brought forth to show the benefit of this treatment in the last two-named classes of disease is in itself quite convincing.

The results of the treatment are a prompt increase in strength, a diminution in the rate of the pulse, a slight slowing of respiration, and a diminution in the size of the heart, which is most remarkable. During this diminution, a systolic, mitral, or tricuspid murmur disappears, the cardiac sounds improve, and the apex beat becomes more forcible. The applicability of the method—it may be given by an attendant, in the patient's own home—the plausibility of its *modus operandi* as well as the testimony that is borne by unprejudiced scientific observers commend it to every intelligent physician.

The obscurity in which rheumatoid arthritis has been veiled bids fair to become dissipated by recent investigations into its bacterial origin. Three years ago, Schüller (*Berliner klin. Wochenschrift*, Sept. 4, 1895), described a micro-organism which he had found associated with rheumatoid arthritis. It was about 2.6 m. long, 0.75–0.995 m. broad, and exhibited marked polar stains. It was easily receptive of the ordinary stains, and grew with readiness on ordinary culture media, such as gelatin and agar-agar. Recently, Drs. Bannatyne, Wohlmann, and Blaxall have made a contribution to the clinical history, etiology, and pathology of rheumatoid arthritis (*Lancet*, April 25, 1896), which is in the line of Schüller's observation, and which, if substantiated, will be epoch-making in the history of the disease. Drs. Bannatyne and Wohlmann were led, from observation of the clinical aspect of cases and from a knowledge of the work that had already been done in the endeavor to elucidate the cause of this disease, to the conclusion that the disease was due to a micro-organism, and, moreover, they had found, by microscopic examination of the synovial fluid from the affected joints, the presence of a constant and distinct organism. Dr. Blaxall was asked to corroborate or deny these findings. After a most extensive and painstaking examination, the latter found that in the synovial fluid of eighteen cases of rheumatoid arthritis there was an organism which was constant in its characteristic. This organism, morphologically, is a minute bacillus, exhibiting marked polar changes and of variable lenth—up to 3 m., or possibly 4 m. It can be grown in culture media; in beef broth it gives the appearance of gold dust, and on agar-agar and serum its growth is almost invisible. It does not grow on gelatin at ordinary temperature. On account of the small size of the organism, and of its slowness of growth, it was found necessary to conduct the experiments on a large scale—250 cc. of the culture medium—so that any changes in the medium might be easily detected.

In severe cases the organism is found in the blood, but as yet it has not been found in the synovial fluid from distended joints due to other causes. Whether or not the bacteriæ are present in the synovial membrane cannot yet be said, as experiments to affirm or deny this have not been carried out.

Although Dr. Blaxall is very positive that the organism discovered by Drs. Bannatyne and Wohlmann is not identical with that described by Schüller, we cannot see that he substantiates his position by any incontestable proof. They are practically of the same dimensions, they exhibit marked polar staining and are easy of decolorization. But whether they are or are not identical, the discovery remains an important contribution to the subject.

There is probably no conviction more firmly settled in the minds of clinicians than the one that associates angina pectoris with and makes it dependent on disease of the coronary vessels. In the last number of the *Asclepiad*, Dr. Benjamin Ward Richardson discusses the nature, cause, and treatment of this affection on the basis of forty-three cases which he has carefully studied. It is be-

lieved that there is not distinct heredity; that men—"troubled" men—who lead a busy, outdoor, vigorous life, and who are of a nervous temperament, make up the vast majority of the cases.

The assumption that in all anginal cases there are certain evidences of disease of the heart, such as dilatation or thickening of the coronary vessels, and an interruption in the coronary circulation, is not conceded by the writer. Analysis of the development, of the presence, and of the after-effects of an attack leads the writer to believe that the disease is obviously allied to an epileptiform seizure. He suggests that angina pectoris is an actual disease, a disease of a paroxysmal nature, and quite as distinct as epilepsy. As epilepsy is an affection of the cerebro-spinal system, he believes that angina pectoris is due to a disturbance—an explosion—in the sympathetic nervous system, and affects all parts under that system. What the precise changes are, cannot be said; but it is probable that the change is in the body of the ganglia, or in a center extending throughout the whole sympathetic supply and causing effects in all parts involved. He thinks that if a powerful electric shock could be sent through the sympathetic system, apart from the cerebro-spinal, the phenomena would be those of angina pectoris.

Suggestions in regard to treatment are those which are already very well known. The writer dilates on the efficacy of iodid of potash and of nitrite of amyl and nitro-glycerin as the most important medicines; but it is in the modes of life, with a purpose of avoiding every factor which is known to precipitate an attack, that respite and possible recovery comes to these patients.

Joseph Collins, M.D.

ECHOES AND NEWS.

Dr. Paul Segond of Paris, France, and his assistant, M. Chauvean, have arrived in New York to attend the American Gynecological Society. Dr. Segond is the originator of the vaginal route as a method of attack in chronic suppurative pelvic diseases of women.

The American Climatological Association held its thirteenth annual meeting at Lakewood, N. J., last week. The attendance, although not large, consisted of representative members from almost every part of the Union, and the session was marked by the discussion of a number of important scientific questions, a solution of which will afford unbounded benefit to the human race. The social features of the occasion were not neglected.

Mayor Strong of New York City approved, last week, a bill granting $30,000 of the city's money to the Flower Hospital. Ex-Governor Flower was present in the interest of this charity which bears his name.

Dr. Edward J. Forster, surgeon-general on the staff of Governor Wolcott of Massachusetts, fell dead of apoplexy upon the deck of a Fall River steamer before she had left her New York pier, on May 15th.

M. A. Ranier has bequeathed 2,000,000 francs for the establishment of a physiological laboratory in Brussels.

Dr. Schwartze has been promoted to the position of honorary professor of otology at Halle.

Dr. John Whitridge Williams has been appointed Associated Professor of Obstetrics at Johns Hopkins University, and is now in charge of that department.

As mentioned last week, cholera is becoming epidemic in Egypt. Alexandria reported seventy-three new cases and twenty deaths on the 16th instant.

Mme. Audifford has presented the French Academy with 800,000 francs, the interest of which is to be awarded, without regard to nationality, for the discovery of a cure for consumption.

The successful serum-treatment of leprosy in fifteen cases is reported by Carrasquilla of Bogota, South America. Marked effects occur after the first injection, and sensibility, appetite, and cheerfulness soon return.

Drs. Casey A. Wood and T. Melville Hardin, both of Chicago, have succeeded the late Dr. James P. Parker of St. Louis, as editors of the *Annals of Ophthalmology*.

A new hospital, erected for the Santa Fé Railroad at Topeka, Kan., has been received by the management of this system and opened for the use of its employés. It is said to be the finest railroad hospital in the world, and was built from monthly assessments of the employés amounting to $100,000.

At the last meeting of the Medical College Association Dr. James M. Bodine of Louisville, Ky., was elected president, and Dr. Bayard Holmes of Chicago, re-elected secretary. No important changes were made in the standard of requirements as already announced by this Association.

A French gynecologist has reported the case of a woman who had been in the habit, for more than twenty years of using a lemon in lieu of a pessary. The effect was quite satisfactory, and no harm appeared to follow the practice.

Professor Germain See, the eminent French physician and therapeutist, died in Paris on the 13th instant. He was nearly eighty years of age. Since the death of Professor Trousseau, whom he succeeded, Professor See

has enjoyed a reputation second to none in France, and his contributions to the world's medical literature have been valuable and extensive,

A British bark arrived at the New York quarantine station from Rio Janeiro reporting five deaths from yellow fever during her voyage. She has been held for disinfection.

Four Sisters of Charity from New Orleans have volunteered to devote their lives to the care of the lepers at Indian Camp, La. They have already been installed in their new mission. where they find thirty-one victims of this disease.

The St. Petersburg Medical Academy has been granted 5000 rubles ($2500) by the Russian Government with which to investigate and perfect Professor Rontgen's discovery.

Dr. Rebecca Porter Page died at Plainfield, N. J., on the 16th instant. She was one of the first female physicians of that State, and was one of the earlier graduates of the New York Medical College for Women.

The University of Pesth has conferred an honorary degree upon Dr. John S. Billings, who is now traveling in Europe. The same degree was conferred at different times upon Lord Kelvin, Herbert Spencer, Max Müller, and James Bryce. Dr. Billings is now librarian of the New York Consolidated Library. He already has the degree of LL.D. from Edinburgh.

Governor Morton has signed a bill relating to the management of the New York State Hospitals (insane asylums) by means of which the present officers retire at the end of this year. This leaves the field open for the appointment of such officers as the politicians may dictate, and into their hands will be given the distribution of $4,200,000.

The corner-stone of the clinical amphitheater of the Medico-Chirurgical Hospital, Philadelphia, was laid on the 12th instant with masonic ceremonies. The oration of the occasion was delivered by Governor Hastings.

The twenty-first annual meeting of the American Gynecological Society will be held at the New York Academy of Medicine on May 26th, 27th, and 28th. Professor William T. Lusk will deliver the address of welcome, and on the morning of the second day, the President, Professor William M. Polk, will deliver his address. The scientific discussions, as indicated by the program, give promise of a most interesting and profitable meeting.

At a recent meeting of the French Congress of Surgery, Dr. Reclus proposed, as a substitute for amputation, a surgical procedure which carries conservatism to a dangerous extreme. His method consists in rendering the injured member absolutely aseptic, in doing which he depends principally upon hot water, 140° F. After this is accomplished, an aseptic dressing is applied that prevents decomposition in any tissue that may fail to revive. When natural lines of demarkation have been established, a very limited amount of operative work will usually suffice to remove the devitalized or useless portion.

In his address as President of the National Confederation of State Examining Boards, Dr. W. W. Potter of Buffalo, N. Y., recently said at Atlanta that he was not in favor of a National Examining Board as had been proposed, but thought all States should be encouraged to established a common minimum standard of requirement, and that when this had been accomplished reciprocity of licensure between them should be considered.

The faculty of Bellevue Hospital Medical College, at its meeting on May 5th, took the following action:

Dr. J. Lewis Smith, in consideration of his long connection with the college, was appointed Emeritus Professor of Diseases of Children.

Dr. George D. Stewart was appointed Adjunct Professor of Anatomy.

Dr. William P. Northrup was appointed Professor of Pediatrics.

The *Journal of the American Medical Association* says editorially: "Notwithstanding the protest of the American Medical Association and numerous other medical and scientific societies, the committee on the District of Columbia has reported a bill to Congress to restrict vivisection in the District of Columbia. Senator Gallinger (homeopathist) of New Hampshire, who has charge of this matter, is on record in favor of absolute prohibition and will probably push it to a final consideration. The time has come, therefore, for the profession throughout the country to awaken to the gravity of the occasion. It must act speedily. No one should delay for a single day to file his individual protest with the Senators and Representatives from his own State."

The year ending with the commencement exercises, last week, has been one of more than usual importance in the history of the Jefferson Medical College of Philadelphia. More modern buildings, for both the didactic and clinical departments, have become necessary, and in meeting these requirements, the question of seeking a new location naturally arose. The determination to enlarge and rehabilitate the present site has been announced.

In Chester, England, there recently died a man who had distinguished himself by appearing before the City Justices 130 times in the capacity of a criminal. His father had been tried 35 times, one sister 67, and another 29 times, making a grand total for the family 347 trials. The estimated cost of these prosecutions was $10,000. This is only one example of inherited criminal propensities, a knowledge of which must extend to the masses before popular opinion will demand that the State shall provide for this class of defectives as is now done for the insane.

The Philadelphia Woman's Health Protective Association and a committee from the County Medical Society are agitating the question of building a pay hospital for contagious diseases in that city. The necessity for such an institution in all the larger cities is

just beginning to find recognition in the eyes of the public. Medical men have long appreciated the hardships attending the present imperfect methods of caring for patients afflicted with such diseases.

IT is interesting to note that for one thousand years, from the seventh to the eighteenth century, the use of the vaginal speculum was almost entirely discontinued. This is attributed to the "influence of the Arabian school, which gained its supremacy at the time when the Moslem conquerors took possession of Alexandria, and burned its famous library by command of Omar, A.D. 642." It is contrary to the Mohammedan creed that any woman should undergo personal examination except by one of her own sex. It would be interesting to know whether our American women, who are placed upon the examining table in almost every doctor's office in the country, are better off than the women who lived in 1690.

ONE of the interesting characters of the fourteenth century, was the sergeant surgeon of Edward III., in 1346, John of Arden. He gives a "Description of ye qualities which ought to be in ye surgeon that performeth any operation in chirurgery:

"First, that he be devout.

Secondlie, charitable to ye poor.

Thirdly, to use few words.

Fourthly, to avoid drunkenness.

Fifthly, to be chaste both in words and gesture, as well as to fear ye not.

Sixthly, not to undertake an incurable disease."

A CORONER of Brooklyn has rendered a verdict, recently, of death by lead-poisoning, the circumstances being, in brief, as follows: The decedent, named Carroll, had been engaged in painting certain apartments with white lead and Paris green. Being an engineer, engaged during the day, he spent his evenings in decorating the rooms of his home. He had painted one room and was about to begin work in another, when it was decided to add more Paris green to the paint and make it a shade darker. The following day he was taken ill, and Monday was confined to his bed. His physician is said to have pronounced Carroll's illness due to painter's colic. Counsel was called, but the combined efforts of the physicians were unavailing, and he died four days later, probably from the joint effects of arsenic and plumbic fumes.

SCRUMPOX.—"Scrumpox" is the English schoolboy's name for a severe form of impetigo occurring among the forwards of Rugby football teams. The "scrum," or "scrimmage," with its close commingling of heads, arms, and legs in indiscriminate confusion, undoubtedly offers ideally favorable conditions for the communication of this disease, which is usually confined to the head and face, and often results in severe suppurative dermatitis, with glandular enlargement.

THE *Sanitary Record* says that a rule of the public schools of Copenhagen requires that each pupil shall take three baths a week in the school building. While the pupils are bathing, their clothes are sterilized in a steam oven. When this practice was first introduced, there was no complaint, but in a short time the parents of the children "protested vigorously, on the ground that it made the children discontented with their dirty clothes, and caused them to complain constantly of the filth of their dwellings."

DR. BOUDINOT CURRIE ATTERBURY, medical missionary of the Presbyterian Church in China, has been honored by the Emperor of China with the Imperial Order of the Double Dragon, Second Degree, a distinction never before conferred on any foreigner, excepting, perhaps, the ruler of some friendly Power. This mark is in recognition of the notable services rendered by the American physician in connection with the work of the Red Cross Society, during the late war.

Dr. Atterbury was born in New York City, and comes of a family long prominent in New York. He studied at Yale College, and took his medical course in this city, under the direction of Dr. Frank H. Hamilton. After he was graduated in medicine from Bellevue Hospital Medical College, of the class of 1877, he went to China under the suspices of the Presbyterian Board, and was assigned to missionary duty in the city of Pekin. He there assisted in the establishment of the Ah Ting Hospital. While there, his work was brought to the attention of the emperor and the royal family. He afterward went to Tientsin, where he is at present. A short reference to the arduous labors of Dr. Atterbury in the Red Cross service was given in a receut issue of this journal.

SOCIETY PROCEEDINGS.

ASSOCIATION OF AMERICAN PHYSICIANS,

Eleventh Annual Meeting, Washington, D. C.,

(Continued.)

(Specially Reported for THE MEDICAL NEWS.)

Friday, May 1, 1896.

MORNING SESSION.

The next paper was

A CASE OF PARASITIC CHYLURIA WITH FILARIÆ SANGUINIS HOMINIS IN THE BLOOD,

by Dr. F. HENRY of Philadelphia, which appeared in full in the MEDICAL NEWS of May 2d.

DR. A. H. SMITH reported a similar case of filariæ in the blood of a patient from South America. There was marked elephantiasis with chyluria, and he had had five severe febrile attacks. The parasites could be found abundantly, both by day and night, but were all dead.

Drs. Meltzer and Theobald Smith added some suggestions as to methods of examination.

DR. HENRY, in closing the discussion, said that filariæ had been removed from various parts of the body, and on account of their size were readily apparent. In regard to Dr. Smith's case, when the parasites were found by day also, they were usually of the West African variety. The "elephantoid" fever is common, and orchites not infrequent. The organism should be treated kindly and made

to feel at home, for the sole danger lay in the fact that the female, if irritated, would abort, and as her imperfect ova are nearly $\frac{1}{750}$ inch in diameter, they are too large to pass through the capillaries, hence block the channels and elephantiasis, chyluria, and abscesses result. The normal ova are perfectly harmless to their host.

By courtesy of Dr. Osler the paper on

DILATATION OF THE STOMACH, ITS DIAGNOSIS AND TREATMENT.

by Drs. Wm. Pepper and Alfred Stengel of Philadelphia, was next read in place of his own. Being quite extensive only a résumé was given.

This condition is much more frequent than has usually been suspected and is never simply "mechanical." The tone of the muscular coat is more important than the size of the organ or position of lower border. In a large series of cases pyloric divulsion had been most beneficial. As to means of diagnosis, the various "splashing" sounds were interesting but difficult to locate; they are decidedly unreliable, the amount of fluid which can be injected is a better test. The gastroscope is neither practical nor reliable and gives poor results. Inflation by gas is best of all preferably by air through tube, as gastric "effervescence" is dangerous in weak stomachs. The borders may then be distinctly seen and the position of *all* of them mapped out which is most important. Motor sufficiency is best tested by Leube's test-meal. Occurrence of acid fermentation is also a valuable sign. The various differential diagnoses were then taken up.

Dr. Henry said that in his experience the best test for gastric cancer was the blood-count, which in this condition will seldom fall below 2,000,000 red cells, a reduction utterly inadequate to account for the anemic cachexia.

President Jacobi thought that a diagnosis could be made between cancer and pernicious anemia by the condition of the blood-cells which in cancer were all of normal shape, while in anemia large numbers of imperfect and distorted forms would be present.

Dr. J. H. Musser of Philadelphia, reported

A CASE OF LEUCOCYTHEMIA..

The patient whose history was uneventful and who presented the typical symptoms of the disease was first seen in June, 1895. His color and general condition were good, his weight 160 pounds. Six weeks later the inguinal glands were found enlarged, and from that time the disease ran a rapid course, death resulting in six months. An autopsy showed little abnormal except general edema, a greenish clot in the right ventricle, an enlarged spleen and some intestinal ulcerations. Blood counts showed 1,700,000 red cells and many large and small (transitional) leucocytes, a number of large irregular red-cells, while nearly twenty-four per cent of the leucocytes were polynuclear. Nucleated red cells were also abundant. Sections of lung and bone were examined and found nearly normal, so that the leucocythemia was apparently of splenic and lymphatic origin, although the blood did not so indicate.

Large amounts of iron were found in the muscles and the liver, which seemed to support the view as to the destruction of the red cells, while the intestinal ulcerations suggested an intestinal origin for the toxemia.

Dr. Welch thought that the polynuclear cells, described in the blood and glands, belonged to the general class of polynuclear or so-called "marrow" cells which, however, were to be found in all the tissues of the body. Their condition was probably due to the rapid "endogenous" budding of their nuclei, and an imperfect attempt at rapid reproduction.

The paper of Dr. I. N. Danforth of Chicago, upon

THE TREATMENT OF PERNICIOUS AND OTHER FORMS OF ESSENTIAL ANEMIA,

was read in his absence by Dr. Lyman. Two well-marked cases of pernicious anemia were prescribed, in both of which iron gave temporary relief but soon became both inert and repugnant; arsenic had a little more permanent effect, and bone-marrow most marked and lasting of all, but could only delay the fatal result.

The question was suggested whether the large amount of iron found in the liver *post-mortem* in these cases might not be due to the excessive use of iron as a remedy. As an intestinal antiseptic naphthol was found much superior to iron. Much relief was derived for a time by the use of an arsenical mineral water from the Tyrol. In the first case bone-marrow became repugnant and a glycerin extract of red-marrow was substituted, with such effect that the hemoglobin increased from thirty per cent. to eighty per cent., and the patient considered herself cured for nearly eighteen months. A relapse then occurred, which was at first helped by red-marrow, but the improvement was only temporary and the patient gradually sank and died. In the second case the patient, who was apparently almost moribund, and in an advanced stage of the disease, was so marvelously helped by the red-marrow that he was up and about his business again in six weeks and regarded himself as cured, but soon relapsed and this time hopelessly.

Dr. A. H. Smith reported a case with all the symptoms of this disease, but there was no deformity of the red cells and their count was down to one million. The man's stomach would not tolerate either iron or arsenic, so was practically on no treatment, when he suddenly began to improve, left the hospital, and went back to work. Relapse occurred one year later, and an autopsy revealed gastric carcinoma.

Dr. Janeway said that sudden improvements without apparent cause were common in these cases. Indeed, most of the "cures" reported were of this class, and death was found to result in a year or two. The only "cure" which in his experience had lasted more than two years, was in a case treated by long-continued use of hemoglobin from fresh ox-blood. It is important to remember that pallor is often absent in these cases, even in advanced stages, the abundance of leucocytes prevents it. The lips are not pale, but "dirty-red."

Dr. Henry corroborated the last observation. Had one case which had remained cured for two years after the use of arsenic to the extreme limit of safety.

DR. CROZER GRIFFITH remarked that the cause of this condition is still unknown, but is probably some form of hemolysis. Certainly, iron is of no value, for there is an excess of hemoglobin in proportion to red corpuscles in the blood and hematin in the tissues already. Arsenic and marrow both stimulate the formation, or transformation, of corpuscles. The only cure is to check the blood destruction, and this often primarily due to an intestinal toxemia.

DR. WEIR MITCHELL then read a positively fascinating paper upon

SOME UNUSUAL FORMS OF BROMIC INTOXICATION,

of which no abstract can give an adquate idea. It has long been recognized that the bromids may increase the unpleasant after effects of epileptic attacks, especially the irritability of temper. This will, in some cases, be accompanied by ptosis and feebleness of the limbs, not rarely more marked upon one side than upon the other, just like some drunkards who can recognize that they are distinctly "drunker in one leg than in the other." Feebleness and dulness so marked at times as to amount to partial imbecility. This was the condition in a girl of seventeen, whose father, an apothecary, on the principle "if a little helps much will cure," had been giving her 150 grains of potassium bromid a day. The fits stopped, the child nearly did the same, lying for days in a state of imbecile collapse, but recovered rapidly when the drug was stopped.

In two children, to each of whom one hundred grains of lithium bromid was given by mistake, a similar, though milder condition developed. There were curious disturbances of memory and they were quite unable to walk, the left leg being worse than the right. In many cases he had seen melancholia and mental depression, even a suicidal degree produced by continued use of the drug. In one singular case a doctor's wife, who had been mildly melancholic for years, on approaching the menopause began to be troubled with marked suicidal tendencies at her menstrual periods. These she confided to her husband and he brought her to Dr. Mitchell, when after much questioning, she confessed for the first time, that ever since a furious attack of sciatica, years ago, she had been taking sixty grains of mixed bromids daily, "for fear the pain would come back." She was advised to stop this practice at once, and to her surprise her next period passed without any unpleasant symptoms, and in a few weeks she was rid of her melancholia entirely. A year later, in the course of a neuralgic attack, she was given 90 grains of bromid by an attendant, with the result that her melancholia returned and lasted until the effects of the dose had passed off. In other epileptic cases the drug would increase irritability of temper to the verge of homicidal tendencies.

Some years ago a young farmer was brought in by his friends with this sort of a history. Dr. Mitchell was then utterly skeptical as to the possibility of such an effect, and in spite of the great reluctance of the patient's family, insisted on putting him upon the usual bromid treatment. The experiment at the end of three days came most perilously near resulting in a tragic homicide, and the doctor was fully convinced without further trial. In two instances young boys were reported by their parents as "ugly" and unmanageable whenever they were taking the bromid, though at other times good-tempered and obedient.

The drug also produced marked maniacal excitement, which rapidly passed away on it's stoppage.

DR. JANEWAY wished to add to this interesting paper three cases of his own of fatal poisoning with imbecile symptoms by bromids, given for epilepsy in doses of three drams, six drams and one ounce per diem respectively. The coroners of New York had also reported two other similar cases to him. He had several times known the excessive use of "bromo-soda" by alcoholics—an altogether too common and dangerous remedy, by the way, in "sobering up"—followed by symptoms strongly suggesting general paralysis. In one case six bottles a day were taken. He was sure that many cases of mental depression in convalescence from typhoid were caused by the bromid given for restlessness.

DR. HARE raised the old historic question, whether the evil effects of bromid was not really due to the potash element, which is in itself a dangerous depressant. Even the citrate of potash, in large doses, had been known to cause collapse. Personally, he would prefer the bromid of soda as safer.

In the use of "bromo-caffein" or "bromo-soda," might not the caffein be partly responsible? He had seen large doses of the latter alone given for heart-disease produce acute mania.

DR. LYMAN remarked that his experience verified the paper, but questioned whether heredity and the presence of the arthritic diathesis might not contribute largely to the production of irritability and mania. Has avoided the potash salts for years.

DR. THOMSON added three corroborative cases, two of which were epileptics. One of these suddenly left home without warning and went on a visit of several days to mere acquaintances, entirely uninvited, while taking bromids. The other, a young lady, deliberately bade her mother good-by upon the street and ran away from her. Both recovered on stopping the drug.

DR. DANA thought that the cry about the poisonous effects of potassium was an exploded bugaboo, or at all events, he was very skeptical as to its basis. In a large experience with both, he had been unable to detect any difference in effect between the sodium and potassium salts. Had seen huge doses of the potash salts given without any serious effects whatever and thought the chief danger was from the bromin alone. Had seen just as severe toxic results from sodium bromid as from potassium bromid. In small doses the effect of the bromids is soothing and cheering and the only danger is from most unnecessarily large doses employed. In his experience three to five grain doses will produce as marked results in most cases as twenty or thirty grains.

DR. MITCHELL, in closing the discussion, expressed his thanks for the valuable additional contributions to the knowledge of this subject. Personally he had never seen any more depressing effects from the potassium than from

the sodium or lithium bromids. He commonly used the latter as being more soluble and this had been the form in several of the cases reported in his paper. He urged that the bromids should be used more sparingly, they seemed to be regarded as the inevitable therapeutic necessity in nearly all nervous affections, and he comparatively seldom saw a case in consultation in which bromids had not been admistered by some one.

AFTERNOON SESSION.

The paper of DR. OSLER

NOTES ON NEUSSER'S GRANULES IN THE BLOOD

was read by title.

IDIOPATHIC OSTEOPSATHYROSIS IN INFANCY AND CHILDHOOD

was discussed by DR. J. P. CROZER GRIFFITH of Philadelphia.

This condition also known as *fragilitas ossium*, is comparatively rare at any time of life, and particularly in infancy or childhood. It is distinct from the bone affections due to syphilis, osteomalacia, and rickets. A case was reported in a boy of two, who, since shortly after birth, had suffered no less than eighteen fractures. So easily were they produced that the child had to be kept lying on a stretcher constantly. His general health and mental development was good. Inheritance is of importance, for although the history in this case is negative, tables show eleven cases in one family, nearly all of whom were males, thirty-four fractures had been reported in one case, and sixty-four in another. One woman's legs would break under her weight or by turning over in bed. Appeared to be an arrest of the normal ossifying process, as even a microscopical examination reveals little abnormal in the structure of the affected bones. No cause known, except inherited tendency. It most nearly resembles "fetal rickets," so-called, which is not a true rickets at all. Bones do not bend as in osteomalacia, but simply snap. Fractures usually unite rapidly. Disease probably produced through the central nervous system.

DR. LYMAN added another case in a young man who, between early childhood and the age of twenty-five years, had suffered thirty-three fractures. The tendency, fortunately, "wore itself out" and disappeared at the age of twenty-seven years. The pelvis and tibiæ were, however, much deformed and bent so as to produce much deformity. He was well developed, but had no sexual appetite.

DR. MUSSER inquired as to the amount of urine passed, as polyuria was common in rickets.

DR. A. H. SMITH mentioned a case of senile fragilitas in an autopsy at the good old age of 111 years. The ribs were cut with scissors, like paper.

The papers of DR. WM. H. WELCH, of Johns Hopkins, upon

BACTERIOLOGIC EXAMINATIONS IN ACUTE ENDOCARDITIS,

of DR. GEO. DOCK of Ann Arbor upon

A CASE OF TRICUSPID STENOSIS, WITH OTHER HEART LESIONS AND CARDIAC LIVER,

were read by title.

DR. WM. H. THOMPSON of New York, read a brief, but suggestive, essay upon

PAINFUL POINTS IN GOUTY COMPARED WITH RHEUMATIC ARTHRITIS.

In twenty-four cases of gout, the disease began, in ninety-eight per cent., in the lower extremities and in the periosteum. The points of change and of tenderness upon pressure are over the condyles, especially in the finger joints.

In fifty-three out of fifty-eight knee-joints attacked by rheumatism, the points of greatest soreness and tenderness were along the line of the tendons; in no case over the condyles. This he believed to be the general rule, except in the elbow- and wrist-joints.

DR. LYMAN stated that a recent English observer had called attention to lateral tenderness as a diagnostic symptom of gout, which he believed to be due to the nerves being involved.

The papers of DRS. C. F. FOLSOM of Boston, upon

THE PREVALENCE AND FATALITY IN PNEUMONIA,

and E. G. CUTLER of Boston, entitled

A CASE OF SUBDIAPHRAGMATIC ABSCESS WITH OPERATION,

were read by title.

DR. WHARTON SINKLER'S essay upon

HABIT CHOREA

was then taken up.

There are two distinct varieties of this disease, one in which it is the result of a mere habit or oft-repeated trick and the other in which some predisposing cause is the chief factor. It is commonest in the muscles of the face and jaws, especially those about the eyes and eyebrows, the zygomatici being next most commonly affected. However, the limbs are also affected at times, even the lower, in which case a jerking gait resembling equine "string-halt" is produced. In one of his cases, a girl of sixteen, walking, would be interrupted every few minutes for the purpose of rubbing the back of one calf with the toe of the other foot. In another the trick of rubbing the eyebrows with the fingers had been so persisted in that the brow was completely cleared of hair. Another patient, a boy of five would persist in imitating the actions of a motorman, in turning on or off the current on an electric car.

Not infrequently some curious atavistic reflexes were noticed such as movements of the ears in connection with those of the nostrils in vigorous sniffling, like the horse or deer. The age of the cases reported varied from one to thirty-seven years, but seem most frequent in the second decade of life. In 34 out of 140 cases heart-murmurs were present and in 35 out of 49 examined errors of refraction were found. The confinement and strain of school attendance strongly predisposes to and aggravates the attack.

The chief principle of treatment is to seek for the local cause, refractive errors, nasal disturbances, local neuroses, etc., and remove this, as drugs are of but little use before this is done. Change of air and arsenic will then be found most useful, but the best results of all are by the modified rest treatment.

Dr. Osler protested against some of the positions taken in Dr. Sinkler's paper; they seemed to him a step backward. Habit-spasms of any sort was an entirely distinct thing from chorea. They were hard to distinguish in some cases but generally recognizable by the fact that it was more obstinate, was accompanied by mental disturbances and very seldom associated with endocarditis. The term chorea has been greatly abused and made to cover a great variety of conditions since it was first used by Burton in his famous "Anatomy of Melancholy." The name, of course, is unimportant, but the two conditions confused in this paper are absolutely distinct.

Dr. Putnam supported Dr. Osler's position. Habit chorea belongs to the class of mental diseases, "Association Neurosis," as Morton Prince calls them.

Dr. Weir Mitchell thought the separation simply a matter of names. The disease group was definite and well marked no matter by what name it was called. For his part the frequent occurrence of heart lesions at least suggested a relation to true chorea.

The President remarked that the principal symptoms of this group belonged to the face, the region of the fifth and seventh nerves and are often nasal reflexes. Most of them begin in children under ten years of age. In his experience nearly ninety per cent. of them recover upon correcting any nasal abnormalities present. Arsenic he had found of benefit as an adjuvant to local treatment in old cases.

The paper of Dr. J. H. Musser of Philadelphia upon

RAYNAUD'S DISEASE AND ERYTHROMELALGIA,

was read by title and will appear in an early issue of the Medical News.

Dr. C. L. Dana of New York, presented a report upon

A METHOD OF CURING TIC DOULOUREUX.

After a vivid description of this agonizing affection, in which everything that the wit of man could suggest, from bromids to surgery, had been used as a remedy, but without permanent or reliable results, he proceeded to describe a method of treatment which had proved very satisfactory in his hands. This consists of three parts. (1) Massive doses of strychnia hypodermically; (2) tonics; (3) rest in bed, with a nearly liquid diet, and large amounts of diluent drinks. The strychnia he begins at one-thirtieth grain and rapidly increases up to one-sixth to one-fourth grain *per diem*, until slight toxic symptoms are produced. He was surprised to find a markedly anodyne effect from these large doses, and often a somewhat somnolent condition, with a stronger, slower pulse. Illustrative pulse-tracings, from some of his cases, were shown. The relief of pain following the injections was in some cases so marked that patients would return later in the day begging to have them repeated. A curious fact was that painful mesenteric spasm was no contraindication to the drug, but was promptly relieved by it. The tonics consisted of heavy doses of potassium iodid and iron. The rest in bed was one of the most important parts of the treatment, and was insisted upon in all severe or obstinate cases. It must be all day long for four weeks, then half the day for two weeks more. A second course of the treatment was sometimes needed, but in no case yet had marked benefit failed to result. The relief from the pain had lasted in his cases from two to five years, the latter being the period during which he had been using the treatment. He regarded the disease as essentially a local expression of general malnutrition, with arterial sclerosis. Surgical interference was regarded as a clumsy cutting of the Gordian knot, and justifiable only as a last resort.

Dr. Putnam thought the interval of cure not long enough to give certainty. In Boston the experience with surgical means had been most satisfactory—far more so than with any other.

Dr. Janeway had secured the best results from aconitia, when he was sure of a good article of the alkaloid, as many preparations were almost utterly inert. This he followed by Croton–chloral, in five- to ten-grain doses.

Dr. Sinkler inquired as to direct effects of strychnia, and thought the general therapeutic measures of more importance than the drug.

Drs. Meltzer, Hare, and Bond added further questions as to methods, the former inquiring as to the possible effect of suggestion in these cases.

Dr. Dana, in closing, replied that suggestion was possibly somewhat helpful in the result. The rest was very important; but one case had recovered without it.

Dr. J. J. Putnam of Boston, read a paper upon

THE RELATION OF MIGRAINE TO NEURALGIAS OF THE FIFTH NERVE.

Migraine was described as a neuralgia instead of a distinct neurosis, as it is usually regarded. It was formerly supposed to be of malarial origin, and it has certain periodic tendencies about it, but is more commonly associated with catarrh of the frontal sinuses than with any other single condition. Hereditary influence plays an important part. The treatment found of most benefit is quinin in large doses about four hours before the expected attack. Arsenic is next in value, and nasal treatment of great importance.

Dr. Thomson regarded the periodic neuralgias as forms of migraine, and thought it often followed influenza.

Dr. Fussell declared that the malarial influence was entitled to considerable weight, as recent observers had discovered the plasmodium in the blood of patients suffering from migraine.

Dr. Hermann Biggs of New York, then presented a report upon

THE VIRULENCE OF THE DIPHTHERIA BACILLI FOUND IN THE THROAT IN CASES PRESENTING THE CLINICAL SYMPTOMS AND TONSILITIS.

We are willing to quarantine cases of scarlet fever until all danger of infection is passed, but not diphtheria. The mildest forms of angina may be caused by true bacilli of diphtheria. These observations had been made upon all sorts of doubtful cases, and whenever bacilli were found, they were cultivated and tested upon guineapigs. In only three out of forty-eight cases in which bacilli were found were the latter non-virulent. Of these cases nineteen were clinically "follicular tonsilitis"

throughout, and twenty-three were so at first, developing membranes and regular diphtheritic symptoms later in their course. Eighteen out of the nineteen "follicular" cases yielded virulent bacilli. Nearly all these cases gave history of recent exposure to diphtheria. The bacilli persisted for from eight to thirty days after recovery. He makes four divisions of cases of diphtheria. (1) Healthy throats in which Loeffler bacilli are present; (2) simple anginas, in which the bacilli are present; (3) typical cases of diphtheria in which bacilli are found; (4) membranous anginas of severe type in which no Loeffler bacilli are present, but which are clinically and for "official" purposes true diphtheria, probably caused by other forms of bacilli.

Dr. Welch remarked that in his laboratory ninety-three per cent. of "suspected" cases of membranous angina showed Loeffler bacilli and nearly the same proportion had been reported by Bolton. All throat diseases where bacilli occur should be classed as diphtheria whether the clinical symptoms develop or not.

Dr. Meltzer wished to confirm the last statement and to add that many cases in which bacilli could not be detected should also be included, as neither their absence nor that of membrance, necessarily disproved such a diagnosis.

The President remarked that in his opinion most of the "simple sore-throat" in epidemics of diphtheria was true diphtheria. He questioned, however, whether every case in which the Klebs-Loeffler germ was present ought to be regarded as diphtheria, for he believed that many of those present probably had such bacilli in their throats and yet were in no danger of diphtheria.

Dr. Biggs in reply stated that the bacilli were not common in healthy throats, only about one per cent. of those examined, except after contact with diphtheria in some way. The throats of the New York Health Inspectors have been repeatedly examined for this form with generally negative results.

The papers of Dr. Osler of Baltimore upon

HEPATO-PULMONARY ABSCESS

and

THE PATHOLOGY AND PATHOGENESIS OF ACUTE AND SUBACUTE DIFFUSE NEPHRITIS,

were read by title.

Dr. Andrew H. Smith of New York, then closed the session with a paper upon

PROGNOSIS IN PNEUMONIA.

The most important factors in determining this are rheumatic, nephritic, and cardiac complications, the use of alcohol being of secondary importance. The temperature cannot be relied upon as a sign; indeed those cases developing very high temperatures often do best. The pulmonary heart sounds are of the greatest prognostic value since death usually occurs from failure of the right heart.

The old "buffy coat" of our ancestors was an excellent sign, as it was a good index of the degree of leucocytosis. This measures most accurately the degree of the resisting power of the system. In 101 cases, the 6 fatal ones all showed a subnormal leucocytosis. In no case in which the leucocytes fell below 14,000 (9000 being normal) did recovery occur. Leucocytosis rises with the temperature and falls with crisis. If, however, an excess of leucocytes persists after crisis, it suggests toxins still remaining in the system, and relapses are very likely to occur.

Dr. Meltzer asked whether bacteriological examinations of the blood had also been made, and was inclined to account for the good results after high temperatures on the ground that these destroy the bacillus lanceolatus (Friedlander's).

Dr. Hare had always been much interested in the influence of fever upon infectious diseases and their bacteria. Fever is unquestionably protective up to a certain point, say 106°, but above that directly dangerous to the tissues. Temperature is also an index of the reactive power of the tissues. Antipyretics diminish production of heat and hence increase the danger.

Dr. Welch thought that no help in prognosis was to be gotten from bacteriological examinations. He believed all cases of lobar pneumonia to be due to the attack of the micrococcus lanceolatus and its toxin the source of danger. The chief factors were the amount of the poison and the resisting power of the tissues.

There was no ground whatever for any theory of the advantages of fever from a bacteriologic standpoint. The growth of the micrococcus lanceolatus was checked only by 46° C. (114° F.) which of course was seldom attained in the human tissues.

SATURDAY MORNING.

The first paper of the closing session was read by Dr. G. M. Garland of Boston, upon

A CASE OF ESOPHAGEAL HEMORRHAGE, WITH CIRRHOSIS OF THE LIVER.

This extended over a course of several years, with a long interval of perfect health between the first attacks and the last fatal series. The hematemesis was so profuse after eating that rectal alimentation had to be largely depended upon. After a number of sudden and severe attacks, upon which treatment had no effect, the active vomiting ceased, but there was almost constant dribbling of blood from the mouth, with tarry stools, and the patient gradually sank, until death occurred, after several days of unconsciousness. No pain or dyspeptic symptoms at any time developed. The autopsy showed a considerable amount of ascites and a gangrenous appendix. The gut was full of blood; the esophageal plexus of veins enormously dilated, and a distinct perforation present. The liver was small and cirrhotic.

Dr. Osler reported two similar typical cases, with profuse hematemesis and bloody diarrhea recurring at intervals for years. In both autopsies the liver was found cirrhotic, the whole portal and abdominal venous system greatly distended, and a persistent "hemorrhoidal" condition of the esophageal plexus with well-marked erosions. The cause of the condition is an attempt to return the blood to the right auricle otherwise than through the liver, the "short circuit" being made *via* the veins of the lesser

curvature of the stomach and the esophageal vessels, and in some cases the anastomosis is successfully established.

Dr. Graham reported the case of a boy who died of hematemesis, in whom the autopsy revealed varicosities of the esophagus, but without any cirrhosis of the liver or abnormality of any other organ.

Dr. Mitchell added another case in a child who died of unaccountable hemorrhage following scarlet fever. The autopsy showed large "esophageal piles" and also a group of dilated veins in the stomach but no disturbances of any other organ.

The President was of the opinion that the hemorrhage must be due to local changes in the vessel walls, mere dilatation was not sufficient to account for it. Local defects in the arterial walls were not uncommon, absence of elastic tissue for instance. Atheroma might also be the cause, especially in a case the age of Dr. Garland's.

Dr. S. J. Meltzer of New York, then made a preliminary communication upon

ABSORPTION IN THE STOMACH,

based upon a series of extremely interesting and ingenious experiments upon the stomachs of rabbits and cats. The absorptive powers of the stomach have been greatly overestimated. Late experiments show that very little water is absorbed from it. His tests were made with solutions of strychnia and hydrocyanic acid. In cats tying the pylorus greatly delayed the appearance of toxic symptoms of both drugs. The control rabbits were killed in twenty to forty minutes by 10 m. gms. of the strychnia solution, while those in whom the pylorus was tied lived from fifteen to twenty hours after doses of 60 m. gms., and then died of peritonitis. Lest this result might be due to cutting off of circulation, injections were made by hypodermic needle directly into the substance of the stomach-wall with rapidly fatal results.

Similar experiments with hydrocyanic acid showed that it was rapidly absorbed under all circumstances, this being due partly to its volatility and partly to its destructive effect upon the cells of the mucous membrane in which numerous minute hemorrhagic and other lesions were produced. Hence Dr. Meltzer concluded that the cells of the epithelial layer were the principal bar to absorption from the viscus in the case of strychnia and other substances. Similar experiments upon the esophagus showed but little absorption occurred there. His conclusions might be summarized:

1. Doses of 10 m. gms. of strychnia serve to cause fatal results in full normal stomach.

2. With pylorus ligated, doses of from 50–100 m. gms. produced no effect for twenty hours.

3. Absorption from esophagus very poor.

4. Absorption from rectum and oro-pharynx very good.

5. Absorption of prussic acid good everywhere on account of its destroying the vitality of epithelial cells and by its volatility.

The President remarked that clinical evidence supported these experiments. He had found that morphia was much more rapidly absorbed frrom the mouth when taken in powder and without water, than from the stomach, especially where any effect upon the bronchial mucous membrane was desired. In some cases its effects would be produced almost as rapidly as by hypodermic injection.

The papers of Dr. J. M. DaCosta of Philadelphia, upon

PROTRACTED, SIMPLE CONTINUED FEVER,

and of Dr. T. S. Latimer of Baltimore, upon

A CASE OF ACTINOMYCOSIS WITH SPECIMENS,

were read by title.

The Committee of Five upon the *Anti-vivisection Bill*, now pending, made a vigorous and able report condemning the bill, which was adopted and ordered signed by the officers and all the members of the Association.

The charts illustrating Dr. Folsom's paper upon

PREVALENCE AND FATALITY IN PNEUMONIA

were then exhibited and excited much interest.

Dr. M. H. Fussell of Philadelphia, gave a brief but suggestive account of modern methods of utilizing

DISPENSARIES IN MEDICAL TEACHING.

Dr. D. W. Prentiss of Washington, D. C., presented a brief report of the findings of himself and Dr. F. P. Morgan, upon

MESCAL BUTTONS (*Anhiroonium Lewinii*).

A series of experiments had been made upon medical students and upon lower animals with the production of some very brilliant color hallucinations, and roseate visions with indescribable sensations of pleasure and buoyancy. It is used by the Indians much as Pommery Sec is by superior races, and seems much to be preferred to the latter, as not only are its roseate coloring effects more brilliant, but there is no "head" to follow, as it produces absolutely no appreciable after-effects of any sort.

Three alkaloids have already been isolated from the "buttons" (tips cut from a pear-shaped cactus), but none of them have proved, in experiment upon guinea-pigs, to be the active principle, and which is now believed to be one of two resenoids which have just been discovered in the plant. It has been found clinically to be a valuable nerve stimulant and antispasmodic, and to possess some hypnotic properties.

The paper of Dr. H. A. Lafleur of Montreal, upon

SYPHILITIC NEPHRITIS,

was read by title.

The following names having been recommended for membership by the Council at the opening session, the Secretary was instructed to cast the ballot of the Association for their election:

Dr. Isaac Adler, New York.

Dr. J. J. Abel, Baltimore.

Dr. D. D. Stewart, Philadelphia.

Dr. Walter Reed, U. S. Army.

The following officers were elected for the coming year:

President.—J. M. DaCosta, Philadelphia.

Vice-President.—F. C. Shattuck, Boston.

Recorder.—J. Minnis Hays, Philadelphia.
Secretary.—H. Hunn, Albany, N. Y.
Treasurer.—W. W. Johnston, Washington, D. C.
Councillor.—I. E. Atkinson, Baltimore.

After a vote of thanks to the Chair for his able and graceful services as presiding officer, the Association adjourned.

AMERICAN MEDICAL ASSOCIATION.

Forty-seventh Annual Meeting, held in Atlanta, Ga., May 5, 6, 7, and 8, 1896.

(Concluded.)

SECTION ON THE PRACTICE OF MEDICINE.

SECOND DAY—MAY 6TH.

DR. J. W. GROSVENOR of Buffalo, N. Y., read a paper on

THE EFFECT OF ALCOHOL ON THE ORGANS OF SPECIAL SENSE,

in which he took the position that since the discovery of ethylic alcohol no marked difference of opinion among physiologists and therapeutists has ever existed as to the depressing action of this agent upon the organs of special sense, when administered in large quantities. By carefully conducted experiment, it has been shown by Dr. Ridge, that the function of sight and of touch, as well as the sense of muscular weight, are diminished and weakened under the influence of small doses, varying from half a dram to four drams. Dr. Scangel came to the same conclusion, after making a series of experiments upon the sense of hearing. A careful consideration of these and other facts, shows that upon the organs of special sense, alcohol is a paralyzer and a depressant, even when given in small doses. The nerve-cells of the special senses are not so very different from the cells of other parts of the nervous system, as to forbid the belief that alcohol acts as a depressant, and not as a stimulant, upon all the tissues of the human body. This is a perfectly logical deduction from numerous experiments and common clinical observation. This being the case, the medical profession of this country should declare its disbelief in the popular doctrine that alcohol is a stimulant, and also should exert its influence upon the laity to diminish its use. The resort to the administration of alcohol for its supposed stimulant action in cases of cardiac depression, or heart failure, especially during anesthesia by chloroform, or ether, is inadmissible, and is based upon incorrect views. Railroad companies should refuse to employ men as engineers unless they are total abstainers from alcoholic drinks.

DR. PLATT of Massachusetts: If Dr. Grosvenor is right in his conclusions, we certainly are very culpable, as public-minded men, if we do not take the action he has suggested.

DR. WEBSTER of Chicago: Conclusions should not be drawn from the effects of alcohol upon the human body in a state of health which would interfere with its use in disease under proper circumstances and in proper doses. It is not true that under all circumstances alcohol acts as a depressant, and is never a stimulant.

DR. YEAGER, Hammittsburg, Ky.: I have employed it in cases of sickness all my life, and find it necessary in certain conditions for which it is usually prescribed.

DR. H. A. HARE of Philadelphia: I cannot sit still and allow to go, without question, on the records of the American Medical Association, the dogmatic statement of the author of the paper that there is absolutely no evidence in medicine to prove that alcohol is a stimulant. From the results of a large hospital experience, as well as some familiarity with laboratory results, I challenge to the fullest the statement that there is no evidence, scientific or otherwise, that alcohol is not a stimulant. I wish to condemn the tendency at the present day to make sweeping statements, and to say either that a drug is good for everything, or to say that it is of no use whatever. That in proper doses in appropriate cases, it is a cardiac stimulant, is a well-established observation in experiment and practice.

DR. BABCOCK, Chicago, Ill.: I believe that alcohol in proper doses is a cardiac stimulant, but in overwhelming doses it is a cardiac depressant, and my views are obtained from experience and not from experiment.

DR. J. A. OUCHTERLONY of Louisville, Ky.: That alcohol is a stimulant is a fact, and I know it. I was amazed by hearing this elaborate paper based upon such imperfect foundation. I cannot believe that the work of Anstie on "Stimulants and Narcotics" was nonsense. The effects of other remedies are known to us by using our sense and judgment, and, by the same test, we find that alcohol is a stimulant.

DR. MINER of Asheville, N. C.: I would ask the gentleman if he should consider it a legitimate conclusion if drawn from the effects of alcohol in unaccustomed doses? We might as well attempt to draw conclusions regarding the therapeutic action of mercury, by observing the effects of a dose of ten grains of corrosive sublimate. The dose must be suited to the case.

DR. HARE: I charge the gentleman to produce one jot or tittle of evidence to prove that the assertion is correct, that the only stimulating effect of alcohol is "by dilating the arterioles, like nitroglycerin." I can prove that it acts as an arterial stimulant by the experiments of Dr. Cerna. I also point out its effects upon heat production. In small doses it increases heat production, while in overdoses it increases heat dissipation. But careful experiment has shown, even in the latter case where an increased amount of heat is given off, there is still increased heat production, the amount of heat-units are above the normal. The effects of alcohol upon the cutaneous capillaries is that of a stimulant and not that of a paralyzing agent. I desire, in conclusion, to again call attention to the danger of absolute dogmatic statements as to the effects of alcohol, of which an instance is seen in declaring that it acts like nitroglycerin as a paralyzer.

DR. HAINES of Chicago: The objection to regarding whisky as a stimulant, I think, is chiefly sentimental and not based upon scientific fact. Alcohol certainly is a stimulant when given in proper doses and under proper conditions.

DR. JENNINGS of Iowa: I cannot believe that small doses of alcohol can act as injuriously as stated. The

dispute seems to have arisen from a popular misunderstanding of the word "stimulant." Like strychnin and opiates, alcohol should be used judiciously. All are capable of doing harm, but when used in proper cases are very useful.

Dr. Hill, Milwaukee: The difference of opinion arises from studying the effects of alcohol as a toxic agent instead of a therapeutic agent, and from its effects in lethal doses and not physiologic doses. There is a law that any agent which stimulates a center when in certain dose, will depress the same center when given in larger doses. The experience of many years has shown that alcohol is a very valuable stimulant, but its effects are modified by the condition of the patient and the size of the dose.

Dr. Grosvener: It is not a matter of sentiment at all. On the contrary, I have given facts and scientific authority for my conclusions that alcohol is a depressing agent upon the organs of special sense. If there is any scientific evidence that can be presented to me that alcohol is a stimulant, I am open to conviction, but the mere fact that it has been regarded as a stimulant by our forefathers is no reason why we should teach it, as we live in a different era and have more exact information upon which to base our opinions than former generations of physicians.

Dr. W. B. English of Pennsylvania, read a paper on

LYCOPERSICUM IN CARDIOPATHIA.

The Nominating Committee presented its report which was adopted, and the following were declared the officers for the ensuing year: John N. Musser, M.D. of Philadelphia, *Chairman;* T. J. Priestley, M.D., Des Moines, Ia, *Secretary.*

Dr. W. C. Weber of Cleveland, O., read a paper entitled

EARLY DIAGNOSIS OF CARCINOMA OF THE STOMACH BY MEANS OF CHEMICAL ANALYSIS OF THE GASTRIC CONTENTS.

The author stated that the absence of hydrochloric acid from the stomach contents was no longer regarded as absolute evidence of cancer. The presence or absence of lactic acid he also considered unreliable. The chemical test he most frequently employed was that of the Congo red. Examination of the blood microscopically he regarded as important to which the knowledge obtained by palpation, percussion, etc., should always be added in our efforts to arrive at an early diagnosis.

Dr. Herrick of Chicago: The reader of the paper made the assertion that Congo red is a test for free hydrochloric acid, but did not mention the fact that Congo red is also a test for any other acid, so that it cannot be relied upon. Boaz makes the statement with reference to Uffelmann's test that it is thoroughly unreliable. I am pleased that the lecturer believes in the value of other symptoms than those relating to the stomach in making his diagnosis of gastric cancer. I think that we fall into grave error when we rely entirely upon stomach contents analysis. The presence of cachexia and the blood examination afford valuable corroborative evidence, even permitting the diagnosis to be made very early.

Dr. Wainright of Missouri: I have been making analyses of stomach contents for the last three or four years and have recognized cancer where there was no clinical diagnosis. I have several times succeeded in making a diagnosis in this way, but never succeeded in obtaining the patient's consent upon this evidence alone sufficiently early for the operation to do good. Later, when everybody notices the cachexia, the patient may consent, but it is then too late for operation. Analyses of the stomach contents incidentally enables us to make a diagnosis between tumors involving the stomach wall and obscure tumors of the abdomen distinct from the stomach.

Dr. Paquin of St. Louis: The subject is one of great importance. I think that we may not be able to make a positive diagnosis by analysis of the stomach contents and a bacteriological test, but examination of the blood will enable us to make an early diagnosis. We can see progress in this disease, especially since early diagnosis permits surgical treatment at the time, when it is alone amenable to such treatment.

Dr. Webber: In reply to Dr. Herrick I would say that he is slightly in error when he said that Congo red responds to all acids. It responds only to mineral acids and is used as a test for mineral acids.

THIRD DAY—MAY 7TH.

A PAPER ON TREATMENT OF CARDIAC DISEASE IN THE QUIESCENT PERIOD,

by Dr. J. W. Byers was read by title and referred.

Dr. Everett Flood of Massachsuetts, read a paper on

INTESTINAL ANTISEPSIS, DIET, AND CASTRATION IN RELATION TO THE TREATMENT OF EPILEPSY,

in which the operation was defended and illustrative cases cited. The operation is less efficient in woman than it is in man. In several cases after operation the patients became more cleanly in their habits and they had a less number of attacks.

Dr. Fenton B. Turck of Chicago, read a communication to the Section based upon

FIVE HUNDRED CASES OF GASTRIC CATARRH.

At first the functions of the stomach are exaggerated, including the secretions, the hyprochloric acid subsequently is similarly affected. The treatment advocated is washing out the stomach, especially with the acid of the "gyromele," which, as it brings away the mucus from the stomach, may be regarded as a valuable aid to diagnosis as well as treatment.

THE DUCTLESS GLANDS,

by Dr. J. M. Marvin of Louisville.

Ductless glands, vascular glands, or glands with internal secretion, as Dr. Marvin prefers to call them, are now attracting much attention in pathology. Some have a twofold function like the liver, in which there is an external secretion of bile as well as an internal secretion, which is equal if not greater in its importance. External secretions are not the most important function of the pancreas. This gland histologically is made up of not only glandular tissue, ducts, etc., but there are scattered

through it peculiar masses of epithelial-like tissue of great vascularity, and this very feature seems to be the clew to follow in the study of the function of these glands generally. If a portion of the pancreas, even of another animal, be grafted into the peritoneal cavity or under the skin, the removal of the entire pancreas will not be followed by the usual symptoms. If the grafted pancreas be removed, then diabetes and death quickly follow. If the grafted pancreas has had its secreting power destroyed by having paraffin injected into its ducts, it will still prevent the occurrence of diabetes.

These facts are very suggestive. It would seem that these highly vascular interstitial islets of the gland are important structures which furnish something to the blood which prevents the undue formation of sugar in the blood and in the urine. This internal secretion perfoundly modifies the carbo-hydrate metabolism of the tissues.

Passing to ductless glands without external secretion, viz.: the supra-renals, thyroid, and the so-called pituitary gland (hypophysis), which are allied histologically and pathologically, we have an internal secretion, which, when poured into the blood profoundly affects nutrition. In pathologic conditions they are alike as one respect, they all show nutritional changes in the skin. Associated with abnormal variations in the secretory functions of the adrenals, Addison's disease occurs; the thyroid hypersecretion results in exophthalmic goiter, diminished secretion in myxedema and cretinism, while akromegaly is in some way related to disease of the pituitary gland. It is further suggested that the Hippocratic fingers and other nutritional changes in the integument and osseous tissues developing in the latter stages of pulmonary phthisis may be due to interrupted function in the bronchial glands.

Dr. Witherspoon of Nashville: The improvement of a case of myxedema in my hands, by the use of thyroid extract, was very marked both physically and intellectually. This method of treatment demands further investigation.

Dr. A. S. Parrish of Boston, presented a paper on

SPASMODIC TERTECOLLIS,

which was read by title.

The section then adjourned.

Section on Children's Diseases.

Third Day—May 7th.

PERTUSSIS AS A NEUROSIS,

by S. J. Radcliffe, M.D., of Washington, D. C.

In this paper the author stated that in fully seventy-five per cent. of cases, the subjects of whooping-cough are neurotics, usually by heredity. The only remedies beneficially affecting the disease are those that have been considered of a constitutional nature, directed to the neurotic element, upon which the pertussis is grounded. Glycosuria is frequently present in cases of pertussis, especially in the severer types of the disease.

The next paper upon

PETIT MAL IN CHILDREN,

was contributed by Louis F. Bishop, M.D., of New York.

Some cases impress one as if the attack of *petit mal* was a development of an epileptic aura, which stopped short of the convulsion, but in some very rare cases there has been a distinct sensory aura preceding the attack of *petit mal*. It is essentially a chronic disease, and therefore it is difficult to formulate the best plan of treatment. However, special stress should be laid upon the care of the stomach, and all those measures included under the name of hygienic management. Bromid in moderate doses has given the best results.

Then followed an interesting article entitled

TREATMENT OF INFANTILE SPINAL PARALYSIS,

by Harold N. Moyer, M.D., of Chicago.

The writer said the cases may be divided into two classes: First, the very severe cases; second, those of moderate severity. The common division between the severe and the graver form is the ability to walk. The treatment should consist in the use of electricity, preferably the faradic current, if you can secure contractions in the paralyzed muscles with the faradic current. If you cannot secure contractions with the faradic current, by all means use the galvanic current, as strong as possible. This treatment must be continued every day for at least a year.

Dr. W. A. Dixon of Ripley, O., reported his

OBSERVATIONS IN CASES OF EPILEPSY FOLLOWING INJURIES TO THE HEAD IN INFANCY, CHILDHOOD, AND EARLY YOUTH.

In the cases cited by the author, as caused by injury to the head, there was no record in the ancestral line of heredity, insanity, inebriety, tuberculosis, or specific infection, and the injury alone remained as the factor.

These papers were discussed at some length.

The subject of

ENTERO-COLITIS

was presented by Dr. Daniel H. Cunningham of Chicago, and

INFANTILE SCORBUTUS

by Dr. Albert H. Burr, Chicago, Ill.

This disease has been only recently recognized in the United States, but soon after the report of the first cases, twenty-six in all, tabulated by Northrup, there have been numerous cases reported from different parts of the country. From this, it would seem, the disease is assuming greater importance, by reason of its increasing frequency in these days of degenerate mammæ, supplemented by the growing indisposition of American mothers to suckle their young, and by the commercial enterprise and ingenuity of man in devising sterilizers and proprietary foods to meet a long felt want in the failing maternal fluid and motherly instincts.

Where the breast milk has failed entirely, or is inadequate, the nearest approach to it is to be found in the modified cow's milk of our modern laboratories, or the home modification of cow's milk after the plans given by Rotch. No continuous administration of any sterilized, pasteurized, peptonized, or condensed milk, or any dry

commercial foods, should be given to the exclusion of fresh or raw elements of diet.

USE OF THE STOMACH AND RECTAL TUBES IN INFANTS, by Dr. W. J. Bell of Atlanta, Ga., was the next paper presented.

By the use of the stomach tube the stomach may be thoroughly cleansed and all the ferment gotten rid of. The author used a tube with a glass funnel at one end, and at the other end a soft catheter, attached by means of an intervening glass tube. The irrigation of the stomach should be continued until the returning fluid is clear. Then the patient should be allowed to rest about an hour before food is given. The same tube may be used for irrigation or for feeding, when necessary. The tube is especially useful in case of poisoning.

In ilio-colitis, gastro-enteritis, fermentative and catarrhal colitis, cholera infantum, and other forms of fermentative and infected bowel contents, most gratifying results are obtained, by high rectal and colon irrigation. The tube should be passed as high as the transverse colon.

Dr. W. A. Dixon, Ripley, O., commended the papers, and especially emphasized the importance of mothers nursing their children.

Dr. J. A. Work, Elkhart, Ind., brought out the fact that the tube acts as an irritant as well as a means of introducing fluid into the stomach.

Dr. Albert H. Burr, Chicago, has found the use of cold water externally and internally far more stimulating than hot water, and would prefer cold water in colonic flushings, since it is better able to cause peristalsis. Following the effect of the poison on the nerve centers, we have first the poisoning, next pyrexia, and third convulsions. The treatment should be, cold bath to reduce temperature, next colonic flushings, then stomach irrigation, and if you think there is anything left, give a good old-fashioned dose of castor oil.

Dr. Harriet E. Garrison, Elkhart, Ind., had found it advisable to substitute Rochelle salt in lemonade for castor oil, because of the unpleasant taste of the latter.

Dr. C. W. Foster, Deering, Me., had usually found the child over the convulsion by the time he arrived, and they remained quiet long enough to get through them a good dose of calomel and castor oil, which seemed to quiet the nervous system. It is all very well for mothers to nurse their children, if the mother is healthy, but often it is not wise if the mother is sickly. There is a great difference in the milk supply of cities and villages.

Dr. E. D. Chesbrough, Providence, R. I., thought a very striking point is the shrinking, anxious expression, found in every case of infantile scorbutus.

Dr. A. C. Cotton, Chicago, referred to a statement, that when a paper is read upon some rare subject, everybody begins for the first time to find that he has a few cases of the same kind. But there is now more scurvy than formerly, due to the fact the country is overrun with artificial foods, persistently advertised by the manufacturers and also by physicians, who ought to know better. In some whole communities exclusive artificial baby feeding is adopted, and the effects are seen in the development of scorbutus.

CIRCUMCISION NOT NECESSARY IN YOUNG CHILDREN,

by Dr. W. B. Parks, Atlanta.

Upon examining a case of long prepuce, a constricting band is found just in front of the glans penis, the action of which pulls downward and forward, lengthening the prepuce. This band, no doubt, is due to an inflammatory process, caused by improper adjustment of the cloths or napkins, keeping the child wet instead of dry.

Treatment without circumcision consists in dilating the prepuce, and breaking up any adhesions of the prepuce. Dilate every second day, leaving instrument in the stretched prepuce from three to five minutes at each operation.

ANNOUNCEMENT.

THE SECOND PAN-AMERICAN MEDICAL CONGRESS.

The Committee on organization of the Second Pan-American Medical Congress has elected Dr. Manuel Carmona y Valle, president; Dr. Rafael Lavista, vice president, and Dr. Eduardo Liceaga, secretary, and has announced November 16, 17, 18, 19, 1896, as the date of the meeting to be held in the City of Mexico.

The most cordial invitation is extended to the medical profession of the United States to attend and participate in the meeting.

Titles of papers to be read should be sent at the earliest practicable date to Dr. Eduardo Liceaga, Calle de San Andres num 4. Ciudad de Mexico D. F. Republica Mexicana.

The date selected is in the midst of the delightful midwinter season when the climate of Mexico is the most attractive to the northern visitor.

The occasion should stimulate the medical profession of the United States to a most cordial reciprocation of the generous patronage accorded the Washington meeting of the Congress by our Mexican confrères.

It should be remembered that the United States is the largest, and in many regards the most important of the American countries and that as a consequence more is expected of it than of any other Occidental Nation. In no particular is this more true than in the maintenance of position in the realm of scientific medicine on the Western Hemisphere. It is, therefore, simply essential that in this Congress—the most important of all Medical Congresses, in its exclusive, yet broad, American significance—the best thought and the best work of the American profession shall be conspicuous in the proceedings.

The zeal and enthusiasm of the Mexican profession and the active interest of the Mexican government are cooperating to make the second Pan-American Medical Congress attractive, important and memorable.

Those who contemplate attending should send their names and addresses at as early a date as possible to Dr. Charles A. L. Reed, St. Leger place, Cincinnati, that the Committee in Mexico may be advised of the probable attendance.

William Pepper,
President,
A. M. Owen,
A. Vander Veer,
Charles A. L. Reed,
Secretary.
International Executive Committee
for the United States.

ORIGINAL ARTICLES.

CÆSAREAN SECTION; SUTURE OF THE UTERUS VERSUS TOTAL EXTIRPATION.[1]

BY HENRY C. COE, M.D.,
OF NEW YORK;
PROFESSOR OF GYNECOLOGY IN THE NEW YORK POLYCLINIC, ETC.

THE presentation of another paper on this subject may appear to be an attempt to reopen an old question, which has been definitely settled by this Society. The subject of Cæsarean section has been so thoroughly studied by our distinguished Honorary Fellow, Dr. Harris, that there remains little more to be said about it, at least as regards indications and results. The same gentleman has shown by his carefully compiled statistics on symphyseotomy how limited has become the sphere of the elective Cæsarean operation. It remains for us to ask whether, in preferring it to a more radical procedure, when performed under absolute indications, we are adopting the same advanced principles which guide us in other departments of abdominal surgery. Lest I may seem to take too radical a position in advocating more frequent resort to total extirpation instead of the more conservative procedure, I would state at the outset that it is my purpose simply to extend the indications originally laid down for the Porro operation in strict accordance with the teachings of modern surgery. The conclusions arrived at, though based upon my own observation and experience, are not new, having been stated in a recent paper by Dr. Edward P. Davis (*Am. Jour. Med. Sc.*, May, 1896), and are offered here in order to evoke a general discussion among those whose opinions carry so much weight.

In the three cases of Cæsarean section which I reported in a former paper (in all of which symphyseotomy was positively contraindicated) the conditions were such that I felt at the time, and have often felt since, that, however successful they may have been from a surgical standpoint, the preservation of the uterus under the circumstances was of doubtful benefit to the patients. One woman, an old multipara, had a small fibro-myoma in the lower uterine segment, which has since increased in size and will eventually require removal, while the patient is constantly in fear of another pregnancy. Another, a miserable tuberculous dwarf (unmarried) did require a second hysterotomy, as I did not see her again until she was eight months advanced. I spared the uterus a second time, but ligated the tubes, and she nearly died from sloughing of the abdominal wound. Between the first and second operations I was obliged to open her abdomen twice in order to separate intestinal and omental adhesions.

The history of a fourth case is as follows:

On February 14, 1896, I was asked by Dr. James Law of this city, to receive into the hospital a patient who had been in active labor (at full term) for eight hours. She was seen by Dr. Malcolm McLean, who expressed the opinion that she could not be delivered *per vias naturales*. She was a primipara, aged twenty-three, who had married a year previously against the positive advice of her physician. She had arthritis of the left hip (presumably tuberculous) at the age of five, from which she suffered for seven years, having had numerous abscesses, with discharge of dead bone, resulting in complete ankylosis, and two inches shortening. Her pregnancy had been normal until the beginning of the last month, when the daily amount of urine diminished greatly, and she had marked edema of the lower limbs. Physical examination: Height, 4 feet 8 inches. Patient extremely anemic, with marked edema of the legs and eyelids. Pulse, 100 and feeble; temperature 99.5° F. Uterine tumor prominent. Uterus drawn upward, and in a state of tetanic contraction, with ring of Bandl marked. Labor pains had entirely ceased. Pelvic measurements: Spine, 7 inches; crests, 7½ inches; external conjugate, 6 inches; true conjugate, 2¾ inches. There was marked lateral obliquity and narrowing of the outlet. The promontory was considerable to the right of the median line, and projected to an unusual degree. Breadth of symphysis, 2 inches. The child appeared to be of medium size, the head presenting O. R. A., high above the brim, the cervix being one-third dilated. It was impossible to cause any descent of the head by external manipulation.

I decided at once that Cæsarean section offered the only chance for the child, and would be fraught with less risk to the mother than craniotomy. Symphyseotomy was, of course, out of the question. The situation was explained to the patient and her husband, who were extremely desirous to save the child. I gave a bad prognosis for the mother.

[1] Read at a meeting of the American Gynecological Society, May 28, 1896.

She was prepared for celiotomy. No urine could be obtained by catheter, but it was evident that her kidneys were seriously affected.

I operated under chloroform and oxygen anesthesia, assisted by Drs. Jarman and McInerny, the former grasping the neck of the uterus after it had been lifted from the cavity. The child (which weighed 6 lbs. 1 oz.) was delivered in the usual manner, and though deeply asphyxiated was revived. The question then arose as to the treatment of the uterus. Although the hemorrhage was slight, the condition of the patient was such that I felt it imperative to complete the operation as rapidly as possible. I believed that I could remove the uterus in less time than I could suture it, and was the more inclined to do this as both ovaries were transformed into cysts the size of lemons. Even if this had not been the case, I would have felt it my duty to prevent the miserable woman from again becoming pregnant. The ovarian arteries were ligated in the usual manner, the bladder was quickly separated and the uterine arteries were tied with the greatest ease. Although the patient was not in Trendelenburg's posture, I never had an easier abdominal hysterectomy. The parts were readily accessible, and the peritoneal folds so loose that they were simply pushed off with the forefinger. Practically no blood was lost. Irrigation with hot saline solution, gauze drainage per vaginam, and closure of the abdominal wound with a single row of silkworm-gut sutures. Time of operation, about thirty-five minutes.

The patient rallied well, but was in a critical condition for several days. The first twenty-four hours she secreted only eight ounces of urine, containing sixty per cent. of albumin and loaded with granular, hyalin, and epithelial casts. Pulmonary edema speedily developed and threatened to terminate fatally, but with careful nursing she was soon out of danger, and her convalescence was subsequently practically afebrile. There was no milk in the breasts. She was discharged during the fifth week, with ten per cent. of albumin in her urine, but no casts, the amount for twenty-four hours being thirty ounces. Both the abdominal and vaginal wounds had healed perfectly at the end of ten days. The patient came to my office two months after the operation in excellent condition. On examination I found that I had unintentionally left a portion of the anterior lip of the cervix. The pelvic roof was as firm as if the uterus had been *in situ*. The child was entrusted to its grandmother, and at once began to fail, being carried off by diarrhea at the end of a month.

In reviewing this most unpromising case, I feel convinced that I acted for the best interests of the patient in deciding upon total extirpation, contrary to the advice of my colleagues. The necessity for rapid work at the time, my doubt as to the aseptic condition of the uterus, and a consideration for the woman's future welfare, all influenced my decision. The question naturally arose: "Would it not have been better if I had adopted the same course in my other cases, where the operation was performed at a time chosen by myself and before labor had begun?" This question suggested this brief paper.

The familiar arguments advanced in favor of suture of the uterus after hysterotomy are: (1) The woman is left with her generative functions unimpaired; (2) The operation is simpler than hysterectomy, there is less shock, and less danger of sepsis; (3) Statistics are in favor of the conservative operation.

If we were considering the so-called elective operation, performed under the most favorable conditions as regards both the patient and her environment, these arguments would be unanswerable. But such cases are often on the border-line, so that it is quite possible that the patient may be delivered subsequently by forceps or version, and, moreover, symphyseotomy now claims a large proportion of them. This leaves us with the cases of impossible labor, in which there can be no doubt as to the indication for celiotomy. In replying to the first argument, it must be admitted that in suturing the uterus we do indeed leave the patient in the same condition in which she was before, but what is her subsequent history? Time was when the surgeon who was able to report a second Cæsarean section upon the same patient was regarded almost in the light of a public benefactor. Repeated section is sufficiently common and successful, but is it, I would ask, a subject for congratulation in this age of progress? Is it not rather a scientific error? I so regarded it in my case.

The earlier editions of our works on obstetrics used to descant on the heroism of those women who were willing to risk their lives a second, and even a *third*, time for the sake of their offspring. Doubtless they are, but what chance do they have for an intelligent choice? Look over the records of these cases, and you will find that the majority of the patients were submitted through ignorance, rather than with the high motive of preserving the child. It seems to me that we carry conservatism rather far when we deliberately expose to the risk of another capital operation a miserable, rachitic dwarf, illegitimately pregnant, whose offspring is predoomed and whose own life is in great danger of being sacrificed to a sentiment, or to a scientific principle, as you will. The desirability of preserving the functions of menstruation and ovulation, whenever possible, is generally recognized, but how often do we sacrifice the uterus and adnexa in the

case of fibroids, which are a far less menace to life than is a second pregnancy in a woman, with an absolute impediment to natural delivery!

Induction of premature labor is, of course, always a possible alternative, but the statistics of repeated Cæsarean operations show that many of these ignorant women do not apply to the accoucheur again until they are too far advanced for its successful application. Craniotomy is too often the necessary result of such attempts at saving the premature child, whose tenure of life is slight at the best.

As to the simplicity of the technic in suture of the uterus there can be no question. That it is unaccompanied by shock is by no means true. In upward of a dozen operations which I have attended there was marked shock in every one, the patient requiring vigorous stimulation. Yet all were in good condition beforehand, and in several, labor had not begun. There is no comparison between the shock in these cases and that in a prolonged hysterectomy for uterine fibroid. Certainly the time necessary to properly complete a Cæsarean section is often greater than in an ordinary hystero-myomectomy. It is granted that sepsis can be eliminated in the majority of cases, at least where there has been no previous manipulation by hands of doubtful cleanliness. But look over our own American records and see how many patients have succumbed to sepsis, even up to this year—not necessarily through any flaw in the technic, but because the operator left a uterus which was already infected. The fact is, that when we are compelled to operate upon patients who have been frequently examined, or subjected to prolonged attempts at delivery, we can never positively eliminate this element of failure, and are obliged to shoulder blame which does not belong to us, and to incur the risk of adding to the unfavorable statistics.

The statistical argument carries little weight nowadays. In my opinion, the former statistics of the Cæsarean and Porro-Cæsarean operations prove nothing, since it is well known that the latter include the majority of the "late" or unfavorable cases. It would be more just to class them under the head of puerperal hysterectomy for septic infection, since the conditions are nearly the same. On the other hand the old Porro operation; with extraperitoneal fixation of the stump, was a crude and imperfect procedure compared with modern total or partial abdominal extirpation. We are making new statistics every year in other departments of surgery, why not in obstetrical?

To return to the alternative—total abdominal extirpation of the uterus and adnexa. The advantages which the radical operation presents are:

1. Rapidity of execution. Any one who has had occasion to perform the operation must have been impressed with the ease with which ligation of the broad ligaments and separation of the bladder can be accomplished as compared with the same steps in an ordinary abdominal hysterectomy. In one of the writer's cases of celiotomy for rupture of the parturient uterus (clamps being used) it required only five minutes, another in which ligatures were used, about ten. It is not necessary to elevate the patient in Trendelenburg's posture. Time is an important factor, especially in cases of women who have been many hours, or even days, in labor, and are in collapse before they are placed on the table. There is no more shock or loss of blood than after suture of the uterus.

2. By removing the entire uterus we are reasonably certain that no infected tissue has been left within the abdominal cavity. In my first Porro case, seven years ago, the patient did indeed recover, but her cervix had been infected before the operation and sloughed out entirely. Free drainage *per vaginam* may save even the most desperate case. No uterine sutures are left to give subsequent trouble, as in reported cases.

3. Neoplasms of the ovaries or uterus, or diseased appendages, are removed at the time, instead of being left to give future trouble. Removal of the adnexa after Cæsarean section, has always seemed to me to be fraught with considerable risk, since the large, soft stumps, with thin distended veins, are exposed to more or less traction during uterine contractions. Fibroids, apparently not large enough to justify a Porro at the time, have been left behind to give subsequent trouble, as in the case cited.

4. Convalescence is quite as rapid as when the uterus is sutured.

In advocating total extirpation of the uterus, under these circumstances, I have no intention of stirring up the old controversy of supravaginal amputation of the cervix *versus* hysterectomy. The results recently reported by Dr. Davis—three operations by which the mothers and children were all saved, are sufficiently convincing to need no comment. Moreover, the similar operation for fibroid tumors in the hands of Kelly, Baer, and many others, furnish statistics which admit of no unfavorable comment. I would only call attention to the fact that Dr. Davis' operations were performed upon patients who could be regarded as positively *aseptic*, so that in dropping the

stump of the cervix he was fairly certain that no infected tissue was left behind to vitiate his own careful technic.

In my own case, and in others in which the surgeon is obliged to operate under less favorable conditions and upon patients who have been subjected to repeated examinations and manipulations, he may well hesitate about leaving the cervix and closing the cavity without drainage. Moreover, the condition of the patient may be such that time is an important element, and I believe that at full term the removal of the entire uterus is a simpler and more rapid operation than supravaginal amputation with such careful suturing of the stump, as is necessary in order to insure a successful result.

In my experience, the objection with regard to weakening of the vaginal roof by removing the cervix is largely theoretical, in puerperal hysterectomy as well as in total extirpation for any cause. I have been looking for a case of vaginal enterocele ever since I began to do the operation, but in an observation of at least one hundred cases in my own practice and that of my friends who practise total abdominal extirpation, I have been unable to find one. Some of the patients have been under observation for two or three years.

To recapitulate: Granting that the indications for Cæsarean section are becoming every year more clearly defined and that the operation will probably be more rarely performed in the future, in every case in which we decide to resort to it we should ask whether we are justified in allowing the patient to incur the risk of a second operation. The way to avoid this risk is to ligate the tubes, to remove the adnexa, or to extirpate the uterus. As experience has shown, the first two procedures do not furnish positive immunity against a second impregnation. Under some circumstances, the surgeon's duty is clear. The presence of extensive disease, or of neoplasms of the uterus and adnexa, bring the case under the ordinary rules of modern surgery. Absolute failure of the uterus to contract after evacuation of its contents (a rare, but not impossible contingency), and undoubted, or even suspected, infection of the organ were long ago recognized as indications for Porro's operation. To this may be added a dyscrasia (as tuberculosis), which renders a subsequent pregnancy highly undesirable. There remains the class in which dystocia is due to marked pelvic deformity.

The wishes of the patient should be considered, when they really carry weight, but I fully agree with Dr. Davis that this rule cannot be universally applied. As he fairly states it: "In women of good constitution and happily married, few will be found who will not desire to retain their power of reproduction. On the other hand, in married women of feeble strength, in circumstances of poverty, the burden of childbearing may well be removed. In women illegitimately pregnant and belonging to the class of professional paupers who are likely to be, with their progeny, a constant burden on the State, the continuance of reproduction is certainly to be avoided. Most of the latter class have little conception of the responsibilities of maternity, and even if asked to make a choice, are incapable of doing so intelligently."

COLPOPERINEORRHAPHY.[1]

By H. J. GARRIGUES, A.M., M.D.,
OF NEW YORK, N. Y.;
PROFESSOR OF GYNECOLOGY AND OBSTETRICS IN THE NEW YORK SCHOOL OF CLINICAL MEDICINE, HONORARY CONSULTANT TO THE NEW YORK MATERNITY HOSPITAL, GYNECOLOGIST TO ST. MARK'S HOSPITAL, ETC.

TWICE I have published papers on the perineum. The first (*American Journal of Obstetrics*, April, 1880) treated only of fresh tears, the second (MEDICAL NEWS, April 25, 1891) gave a detailed description of the anatomical relations of all so-called lacerations of the perineum, old and fresh. To-day I wish only briefly to recall the chief anatomical facts of these lesions in general and give a detailed description of one operation for the most common of them.

The old authors used the expressions *vulva*, *matrix*, and *uterus* to designate the whole genital tract from the rima pudendi to the fundus uteri, and laymen now frequently use the word *womb* in this sense. While every scientific writer nowadays distinguishes the uterus from the vagina, many still confound the latter with the vulva, although there is as distinct a limit between the two latter as between the two former, the line of demarkation being the hymen or its remnants, the carunculæ myrtiformes.

There are at the perineal region three rings which are of importance in the understanding of perineal lesions, the vulvar ring—or rima pudendi; the vaginal ring—or introitus vaginæ—and the anal ring. Any of the three may be ruptured separately in childbirth, or the injury may involve two or all of them.

Of all the muscles contributing to the formation of the vaginal ring, the *levator ani* is by far the most important. It forms a horseshoe-

[1] Paper read by invitation at the Fiftieth Anniversary of the University of Buffalo, N. Y.

shaped expansion, which is open in front, is attached in a wide circumference to the walls of the pelvis, and forms a double loop behind the vagina and the rectum.

This muscular expansion, a true pelvic diaphragm, is covered above and below with a fascia; above lies the rectovesical fascia, which is a part of the pelvic fascia, and below the anal fascia, which is a part of the deep perineal fascia.

Between the vulvar and the vaginal ring in front and the anal ring behind lies the perineal body, which forms the center of the whole perineal region, where muscles, fasciæ, and ligaments come together. As these are fastened themselves to the surrounding bones, the perineal body becomes the chief support of the pelvic floor.

I have chosen colpoperineorrhaphy for the subject of this paper because it is the remedy for the most common of the tears near the outlet of the parturient canal and because, through a mistake in the publisher's office, the figure in my work on "Diseases of Women" meant to illustrate the operation is defective.

The deep tear of the vaginal ring, implicating the levator ani muscle and its fasciæ is usually found backward and outward in the direction of the tuberosity of the ischium, the reason of which is probably that the muscle is caught between this point and the head, while in the median line the intervening rectum and the double fascia that descends in front of it as a continuation of the pelvic fascia furnish a soft pad which protects the muscle. The break is much more common on the right than on the left side, which probably is due to the preponderance of the first position of the vertex presentation. The occiput escapes under the rami of the left pubes and ischium, while the broad forehead continues to press in the opposite direction on the posterior wall of the vagina.

Sometimes, however, the edge of the A-shaped break in the levator ani can be followed behind the rectum over on the opposite side. Sometimes the tear is submucous, the muscle snapping while the more elastic mucous membrane stands the strain.

A tear involving the levator ani and its fasciæ deprives the pelvic structures above of the necessary support. As soon as the patient gets up from childbed she has a disagreeable feeling of looseness and bearing down. In course of time the mucous membrane bulges out in front and behind, the bladder sinks down, the uterus is first retroverted, then retroflexed, then it descends, and may finally hang, surrounded by the inverted vagina, between the thighs. The strain on the utero-sacral ligaments, the broad ligaments, and the connective tissue of the pelvis, causing pain in the sides of the pelvis and backache. The displacement interferes with free circulation in the pelvis, causes a sensation of heaviness, and produces hyperplasia of the uterus. The vagina is inverted, the cervix is often drawn out to a great length, its lips everted, and often ulcerated.

The prolapse of the anterior wall is correctly called *cystocele*, because almost always the bladder, being fastened to the vagina with short, resistant, connective tissue, is drawn down with it and lies in the anterior swelling.

The prolapse of the posterior wall is erroneously designated as rectocele. I say erroneous, because the rectum nearly always stays in its normal place, while the vagina slides away from it, the connective tissue here being much looser and laxer than that between the bladder and the vagina.

For this condition of a broken vaginal ring, with a more or less pronounced prolapse of the posterior wall of the vagina, whether combined with a tear of the vulvar ring or not, I think colpoperineorrhaphy is the best operation.

The operation consists in the removal of a triangular piece of the mucous membrane of the posterior wall of the vagina and the vulva, in the folding in from side to side of the denuded surface, and in the elevation of the posterior wall toward the anterior.

Preparation.—The patient's bowels are emptied by means of a heaping teaspoonful of compound licorice powder, given the evening before the operation, and an enema of a quart of soap-suds, given at least six hours before the time set for the operation.

The hair should be shaved off the labia and the anus, but may be left undisturbed on the *mons veneris*. The vulva and the vagina are scrubbed with tinct. saponis veridis, followed by several quarts of a solution of bichlorid of mercury (1–2000).

The patient is placed in the dorsal position and her feet raised, with more or less bent knees. In private practice I use Robb's leg-holder for the purpose; in hospital practice, the feet are fastened to uprights with stirrups.

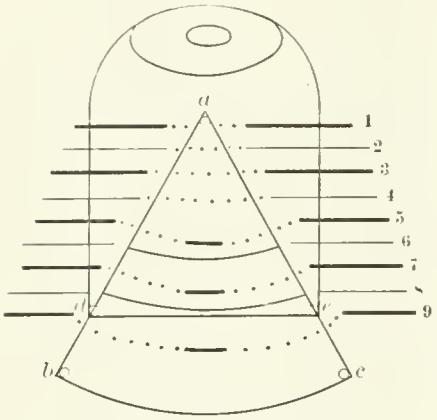
The operator sits in front of the field of operation and an assistant stands on either side, in order to sponge, irrigate, stretch the tissues, and help in inserting the sutures.

The operation should be performed with almost mathematical exactitude, beginning by placing certain landmarks.

A point is chosen on the mucous membrane of

either labium majus, near the edge of the same, and at such a distance from the clitoris that after the operation an opening is left of suitable size for copulation. These two points (*b* and *c*) are

Fig. 1.



Denudation and vaginal sutures.

marked by making a small nick with curved scissors in the mucous membrane.

Next the assistants spread open the vulva and vagina by pulling the labia majora apart in a transverse direction. The operator chooses a point in the median line of the posterior wall, as high up toward the cervix as the prolapse goes (*a*), and seizes it with a bullet forceps with catch, pulls it forward and upward, putting the mucous membrane on the stretch, and leaves the forceps in the hands of the assistant to the left of the patient. Next he draws imaginary lines from this point to the two nicks on the labia majora, and where these lines intersect the lateral furrow of the vagina (*d* and *e*) he inserts another bullet forceps, or preferably a strong tissue-forceps, which does not tear out so easily as does a bullet-forceps, or, still better, a tenaculum-forceps.

Next, a small hole is cut in the mucous membrane just inside of the two lateral pairs of forceps. A pair of blunt scissors, curved on the flat, are introduced closed through the opening on the left side, with the concavity turned toward the operator, and pushed up to the median forceps, and then across to the other side and out through the opening there. Next this triangular flap is cut loose on both sides. If an artery spurts, which is exceptional, it is compressed with pressure-forceps or tied with fine catgut.

Next, the scissors are entered through the opening on the left labium majus (*c*), and pushed up to the forceps in the lateral furrow (*e*), and down to the line of demarkation between the mucous membrane and the skin (*b c*), thus loosening the whole mucous membrane on this side.

Next, the scissors are entered through the opening on the right side (*b*), and this half is loosened and, finally, the whole piece is cut loose along the edge (*e c*, *c b*, *d e*).

While the upper part of the triangle is loosened very easily, there are often cicatrices in the lower part, which have to be severed with small nicks made with the opened scissors.

This way of denuding penetrates much more deeply than if only a superficial layer is cut off from the mucous membrane, and it causes less hemorrhage than if the same amount of tissue is removed with the knife.

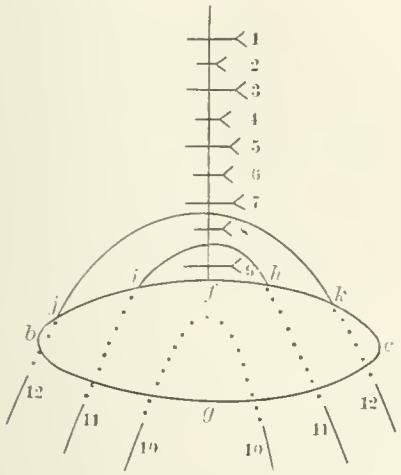
The second step in the operation consists in the insertion of sutures. I use silk, braided No. 4 for the deep vaginal, braided No. 2 for the superficial vaginal, silkworm-gut for the deep perineal, and fine catgut or silk for the superficial perineal. Large curved Hagadorn needles are very serviceable for all the sutures.

The sutures are put in from side to side, beginning from the top of the triangle (*a*), alternating deep and superficial ones (1 to 9, dark lines, deep sutures; light lines, superficial), and leaving a quarter of an inch between two and two sutures. They are tied immediately and cut short. The superficial (2, 4, 6, 8) go only through the edges of the mucous membrane. The deep ones go in the upper part horizontally from side to side and under the whole surface. When the surface becomes too broad, the needle is brought out a quarter of an inch from the median line and inserted on the corresponding point on the other side. The sutures are also placed in a slanting direction (5, 7, 9) so that, when tightened, they lift the posterior wall up, having a resisting point behind where the lateral sulcus is yet fastened to the pelvic bones with fasciæ. Thus we proceed all the way down until the distance from the last suture to the landmark on the labia (Fig. 2, *f c*) is equal to that from the latter point to the median line, following the skin (*c g*). About five deep and four superficial sutures are needed. This leaves us a surface to be used in forming a perineum.

For this purpose, three sutures are inserted from the skin. The first (10) enters about half an inch from the median line and three-eighths of an inch from denuded surface, and is carried all under the surface about two-thirds of the distance up to the lower end of the closed line of sutures (*f*). The second (11) is inserted midway between the first and the third, and is brought out on the upper edge of the denuded surface, between the inner and middle third of its length

(*h*), reinserted at the corresponding point of the opposite side (*i*), carried under the denuded surface and out on the skin. The third (12) is inserted outside of the outer end of the wound (*c*), carried under the denuded surface, brought out on the upper edge between the middle and outer third of its length (*k*), inserted at the corresponding point of the other side (*j*), carried under the denuded surface, and out through the skin outside of the right end of the wound (*b*). These

Fig. 2.



Vaginal sutures closed. Perineal inserted.

three sutures are seized singly with forceps as soon as each is put in, but not tied until all are in place, and the surface has been well irrigated.

The direction given to the sutures insures a very perfect adaptation of the edges and makes the surfaces brought in contact with one another sufficiently broad to form an excellent substitute for a perineal body.

In order to obtain union of the skin, which is always the most difficult, I introduce a couple of superficial sutures between the deep perineal sutures. (Fig. 3. 1, 2, 3).

As the deep sutures are passed close up to the rectum it is necessary to guide the needle with a finger introduced into that viscus. This is much against the rules of aseptic surgery, but of two evils the lesser should be chosen, and by washing the finger in a solution of bichlorid of mercury each time it is withdrawn from the intestine, the danger of wound-infection is at least diminished. As a matter of fact I can state that all my cases, and I have operated on a considerable number, have healed by first intention.

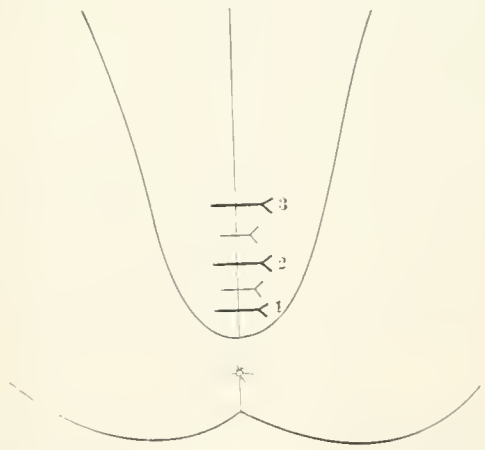
The perineum is covered with a pad of iodoform gauze and plain sterilized gauze kept in place by a T-bandage, and the knees are tied together.

After-treatment.—The patient is kept in bed for two or three weeks. At first there is usually some pain calling for small doses of morphin, but opiates should be avoided as much as possible as they produce hard stools. The urine is drawn with catheter for the first few days. On the morning of the fourth day the bowels are moved with three fluid drams of castor oil, and when the patient feels that she is going to have a passage four ounces of olive oil are injected into the rectum. After that about two fluid drams of castor oil are given every morning, enough to have an easy movement once or twice in twenty-four hours. Before the bowels have been moved the diet should consist exclusively of albuminoid food, such as milk, eggs, beef juice, and raw oysters, so as to have as little fecal matter as possible. Later the patient is allowed full diet.

She may lie on her back or on her sides, but should move slowly and be assisted by a nurse in turning over. The knees should be kept tied together for two weeks, but not tighter than to allow some movements, the object being only to prevent so much spreading of the thighs that the perineal sutures are strained.

The dressing is changed daily. When there comes some sero-purulent discharge, vaginal injections with carbolic acid or lysol should be given twice a day. If the discharge is bloody, liquor ferri chloridi, half a teaspoonful to a pint of water should be given three times a day.

Fig. 3.



Perineal sutures tied.

In order to avoid the formation of a perineal fistula, I remove the middle perineal suture on the fourth day. The two other perineal sutures are removed on the eighth day, the vaginal sutures at the end of three weeks. For this last part I introduce a virginal Sims' speculum under the symphysis pubis.

The patient should be cautioned not to have sexual intercourse for two months.

The objection has been made to operations of this kind that they bring together parts which normally are not united. That is true, but since we cannot repair the damage made in the levator ani muscle and its fasciæ, we must be content with supplying a substitute for the original support. The operation produces a solid perineal body and one which is suspended from the pelvic bones above, just as in the normal relations.

The results show the value of the operation. The bearing-down pain and the headache cease immediately. I have seen cases again after years and found them in excellent condition. I have even confined patients upon whom I had operated. Then, of course the perineum is partially torn, but we get only the two well-known triangles, that are so common in primiparæ, and which are easily brought together with three perineal sutures put in as described above.

My operation differs from Hegar's in the following points: (1) The blunt, deep denudation. (2) The slanting direction of the vaginal sutures, which lift the posterior wall up against the anterior. (3) The slanting direction of the perineal sutures, which insures a more perfect adaptation of the edges.

Combination with other Operations.—Often the injury present demands other operations which may be performed at the same time. If the cervix is torn, it should be repaired and stitched with chromicized catgut, since it would jeopardize the perineum to stretch it with a speculum sufficiently to remove cervical sutures.

If there is a cystocele I use Stolz's operation—circular denudation and purse-string suture. If there is retroflexion I combine colpoperineorrhaphy with Alexander's operation—extraperitoneal shortening of the round ligaments.

CONCERNING BRIGHT'S DISEASE.[1]

BY G. J. TWEEDY, M.D.,
OF WINONA, MINN.

THE early history of medicine, as of all sciences, shows a tendency to differentiate rather than to generalize, due, in large measure, to the fact that clinical phenomena formed the sole basis of medical study, while pathological knowledge was slight. At the time of Bright the anatomico-pathological basis was in vogue, with the anatomical element decidedly in the front. Bright's disease was, therefore, at that time purely a disease of the kidneys. An increased knowledge of the pathological processes involved, and the intimate relation existing between all the organs of assimilation and excretion and the vascular system, has led to a gradual increase in the comprehensiveness of the term in both the causative and pathological lines. At present we know that all forms of Bright's disease are secondary and often directly dependent upon previous disturbances in the general processes of assimilation and retrograde metamorphosis, or as excited by some blood poison. Every form of the disease is directly traceable to an irritant brought to the kidney by the blood, or to mechanical disturbances of the circulation which affect other organs as well, or to a combination of the two. The most constant and diagnostic symptom of this condition is the presence of albumin in the urine; but this alone is not to be relied on, as Bright's disease may exist without albuminuria; and on the other hand albuminuria occurs in a great many instances which are not Bright's disease, and rapidly terminate in complete recovery.

Albuminuria may be divided into physiological and pathological, and it becomes an exceedingly important point to determine when albumin in the urine is significant of organic change, as well as to ascertain what relation so-called physiological albuminuria may hold to subsequent changes. The passage of albumin from the blood into the urine is dependent upon some functional failure on the part of the epithelium of the glomeruli. This is easily understood when some inflammation or degeneration exists, but in cases where the albumin is due to nervous influences or to maintain an equilibrium in the nutritive elements of the blood, and we say that it is a "temporary functional disturbance," such an expression does not convey to my mind a very clear idea of what really takes place. I presume the solution of it can only be clinical.

An albuminuria occurs: (1.) In all the distinctly infectious diseases, and is due to those chemical products of bacteria known as ptomaines, probably assisted by the high temperature, vitiated blood, and disturbed circulation. (2.) It is caused by irritating drugs, such as cantharides, turpentine, etc. (3.) It occurs in certain diseases of the brain and cord. (4.) In some chronic diseases marked by certain changes in the blood, and in mechanical disturbances of the renal circulation, such as tumors.

The albuminuria brought about by pregnancy illustrates the part played by irritants in the blood and pressure on the circulation; the enlarged uterus

[1] Read before Winona (Minn.) County Medical Society, April 7, 1896.

causes obstruction to the circulation and consequent hyperemia and hyper-excitability. The tissue changes in the growing fetus are exceedingly rapid, so that the extra amount of excrementitious matter removed by the maternal organs, is increased in far greater ratio, than it would be if her own tissue were increased by an equal amount in weight; thus we have not only the hyperemia of pressure, but also of excessive activity and direct irritation set up by the increased excrementitious matter. A very large percentage of all these cases rapidly recover when the cause or causes are removed, but if the irritation or disturbance be kept up too long, or a predisposition inherited or acquired exist, degeneration and destruction take place. Bright's disease may then be defined as a "non-suppurative inflammation of the kidney, with manifestations determined by its etiology, the special elements affected and the inherited tendencies of the patient;" but the heart, blood-vessels, liver, and kidneys are so intimately related, that it is impossible to consider one without the other, and in order to get at a proper basis let us consider blood-pressure.

In early life there is a low blood-pressure and a rapid pulse-rate. This low blood-pressure is due to the fact, that the arteries are large in comparison to the heart and the length of the body, and the rapid pulse-rate is due to the shortness of the circuit traversed by the blood. These conditions prevail during early life, more especially the first year. During this time growth is rapid because of the fluid food with which every part is flushed, and the whole body grows in every part, but the growth of the arteries in caliber does not keep pace either with the growth of the body in length, or with the growth of the heart in size and strength. The natural result is a gradual rise in blood-pressure and an equally gradual slowing of the pulse-rate, until early manhood when the growth is complete and the blood-pressure reaches its highest normal. But as development progresses, the arterial coats slowly undergo a change of structure, by which they lose their elasticity and become gradually converted into more or less rigid tubes. The effect of this loss of resilience in the arterial coats is that while these coats yield as formerly to the advancing blood-wave, they yield more slowly and they do not entirely recover themselves, so that the lumen of the arteries undergoes a gradual dilatation. From the dilatation of the arteries there is a tendency to lowering of the blood-pressure, but the cessation of active growth makes a large network of capillaries unnecessary and many of them obsolete, giving rise to the wrinkled skin, gray hair, and other evidences of age. But, by the time the heart has succeeded in permanently dilating the inelastic arteries, and has restored them to their former relative size the increase of the peripheral resistance due to the withering of the capillaries is sufficient to counterbalance any material lowering of the pressure; but, generally speaking, in health there is a slight fall in the blood-pressure as age advances.

We always have an increased blood-pressure during and preceding Bright's disease, the nephritis being merely concomitant and secondary to the general systemic disease. A case of Bright's disease that means not only a degeneration in the kidney but in the vascular system generally, there is quite sure to have been a previous stage of increased blood-pressure with hypertrophy of heart and blood-vessels. The most frequent cause of increased blood-pressure is undoubtedly irritation by some foreign elements in the blood, or an excess of normal elements demanding removal. Irritation is but a step beyond stimulation, and degeneration is the direct consequence of excessive activity, so that all those elements which excite normal action of the kidney and blood-vessels may, when in excess, lead to inflammation and degeneration. Of these the most frequent, the most persistent, and the most injurious, is uric acid. Or, to reverse the order, and give it as it occurs: over-indulgence in nitrogenous foods, uric acid in excess, increased blood-pressure, hypertrophy of heart and blood-vessels, degeneration and disintegration. This hypertrophic condition preceding the degeneration, takes place in the muscular coat of the blood-vessels which has been developed as a conservative process and has become converted into a pathological one secondarily. This illustrates a truism we should never fail to recognize, viz., that many processes which we call pathological, and which, in their fullest development, tend directly to death, are at the beginning strictly conservative, and should be recognized as nature's measures for bringing about a cure.

But all persons who have an increased blood-pressure with an irritant in the blood more or less constant, do not have Bright's disease. There is another important factor in the causation, and that is a peculiar fibroid diathesis inherited or acquired. Thus, Bright's disease may be said to occur in two classes of cases.

1. Those suffering from a peculiar condition in which all forms of irritation tend to the induction of fibroid inflammation, not only under a stimula-

tion (which in other individuals would produce only a healthy nutritive activity), but even in what would be considered purely physiological conditions.

2. Those in whom, either through an inherited or acquired functional weakness of the organs of direct and retrograde metabolism, or on account of intemperance in food or drink, the kidneys are for a long time called upon to eliminate both an excessive quantity of the normal elements of excretion and also products of faulty metabolism.

Since tastes, habits, and moral qualities are inherited as well as physical defects, we often find individuals with the weak power of metabolism following up those perverted habits which brought about those weakened conditions of their ancestors, until eventually a set of individuals is developed who combine a marked fibroid diathesis with functionally weak livers, hearts, blood-vessels, and mucous membranes, and for whom we can predict a premature death, from either apoplexy, cardiac failure, or Bright's disease, unless prevented by a proper regulation of habit and diet.

I have endeavored to treat this subject from its causative and pathological point, and to illustrate the underlying principle, rather than to simply state facts; and in the treatment, I shall continue in a general way, without going into the individual forms of the disease. As a matter of course, the treatment of amyloid degeneration coincident with prolonged bone suppuration or syphilis, would vary in detail from the treatment of acute Bright's disease subsequent to an attack of scarlatina; but I think the principle involved is the same.

The preventive treatment will begin long before the appearance of albuminuria or dropsy. When the patient comes with the uric acid diathesis, complaining of headaches, depressed feeling, attacks of irritability, tendency to rheumatism and gout, then is the time to begin the prevention of Bright's disease by a proper regulation of food, drink and habits, suitable to maintain a condition of health with the least possible amount of irritation. Here I should like to read from Balfour's work on the senile heart, a statement also applicable to diseases of the kidney. "Moderation in all things is the true secret for preserving a sound mind in a sound body, and, if it be not a certain passport to longevity, it at least enables us to live healthily for as long as we may. In these days when every doctrine is a fad and gets pushed to an extreme, there are multitudes eager to enforce a rapid teetotalism upon all their fellow-men, as the only panacea for health, happiness, and longevity. But if we except the votaries of vegetarianism, which is more of a cult than a protest against excess, I know of no society that inculcates by precept or example, temperance in regard to food; yet there is nothing ages a man or woman so rapidly, there is nothing that shortens life so certainly, and there is nothing that embitters the latter days of life so much as over-indulgence in food." Bearing in mind the physiological process of digestion of the various foods, and which bear heaviest on the different organs of digestion, it will usually be not difficult to formulate a diet that will insure the least possible amount of irritation in the blood. If the disease becomes established we find several indications presented for consideration.

In relieving the kidney, both from functional activity and the irritation of its products, of excreta—normal and excessive—acid urine and partially converted elements of retrograde change, the two available channels for vicarious elimination of urea, are the bowels and skin. The bowels are the more important channel, and for its successful accomplishment two things are necessary: an active condition of the bowels, and some element which shall render the excrementitious matters as soluble as possible. Calomel is to be preferred. Its action may be regarded as threefold. The increased hepatic activity results in a more complete metabolism of the waste materials in the blood and their partial excretion in the bile. The total quantity remaining in the blood for further removal is thus not only lessened, but the metabolic processes are more complete, and the elements of excretion are rendered more soluble and less irritating to the kidney, the bowels, and the skin: urea being much more readily eliminated than uric acid. And, lastly, the cathartic action of the bile is entirely sufficient for the rapid removal of all the intestinal excretions, at the same time that its antiseptic action prevents any tendency to ammoniacal decomposition in the intestine.

During this time, waste of water and albuminous elements must be freely compensated for. Elimination of urea being not only favored by high dilution, but it becomes far less irritating. The restoration of the lost albuminous elements is best accomplished by the free use of milk. When, however, dropsy is to be reduced by the bowels, entirely different conditions prevail, and instead of calomel, a highly irritating cathartic, producing watery evacuations, is more desirable. For producing activity of the skin, the hot-air bath is most desirable. The use of philocarpin is generally

contraindicated except, perhaps, in an urgent case of uremia or pulmonary edema developed suddenly. The bowels and skin, being attended to properly, they should be regarded as merely palliative or adjuvant to more direct treatment of the kidney.

In the kidney there are three indications: First: To remove as far as possible the inflammatory products, degenerated epithelium and cellular infiltration of the tubules, by increasing the amount of watery elements in the urine and flushing out the kidney. For this pure water is best, of drugs digitalis is best, and had better be combined with an alkaline water until the quantity of urine is increased. The activity of the kidney and the mechanical removal of tubular *debris* are retarded by the congestion of the kidney, and this gives us the second indication, viz., the relief of congestion. This is best accomplished by hot applications to the loins. Poultices or hot-water bag, by equalizing the circulation, favor and assist the action of the remedies mentioned. The third indication concerns the effects of the retained excrementitious products upon the nervous system. Special reliance is to be placed on hypodermics of morphia and enemata of chloral hydrate; only in extreme cases are anesthetics required. In addition to this, in the chronic forms of the disease, especially the so-called parenchymatous form, iron tonics and cod-liver oil should be employed to arrest, if possible, the degenerative changes and tone up those parts of the kidney which are still healthy, or in which the degenerative processes have not rendered activity impossible.

CLINICAL MEMORANDA.

A CASE OF INTESTINAL OBSTRUCTION. OPERATION, AUTOPSY, AND PATHOLOGICAL REPORT.

By T. A. FELCH, M.D., and CARL C. WARDEN, M.D., of Ishpeming, Mich.

An Englishman, laborer, aged twenty years, was first seen by Dr. Felch in May, 1895. Family history negative. The patient had been blown some distance, through a window, by the force of an explosion, falling upon the buttocks. He complained of pain in the left iliac region and of constipation. Examination elicited pain, and revealed a soft tumor in the region of the sigmoid flexure, due to an accumulation of flatus. A dose of magnesium sulphate relieved all symptoms. Subsequently the patient had repeated attacks of a similar nature, with symptoms more aggravated, and seemed to lose weight. Catharsis always brought relief. On October 1, 1895, Dr. Felch found the patient pale and cachectic, eyes bright, features anxious in expression. Dorsal position with knees flexed on the abdomen. Tongue large and flabby and coated with a brown fur. Respirations shallow, rapid, and costal. Temperature 104 F.; pulse 120. Abdomen enormously distended and tympanitic. Vomiting fecal in character. He complained of pain all over the abdomen, and could not bear the weight of the bedclothes. Had had no movement of the bowels for twenty-seven days, but occasionally passed a little flatus. Rectal examination revealed nothing.

The diagnosis of intestinal obstruction, with probable seat of obstruction at the sigmoid flexure, was made. Copious enemata were given, without effect. Operation was advised as a last resort, and eagerly accepted by the patient.

The abdomen was opened in the median line by an incision extending from an inch above the pubes to a point midway between the ensiform cartilage and the umbilicus. Coils of enormously distended and greatly congested intestines presented, and were covered with hot, sterilized towels. The cecum was full of gas, and the ascending and transverse colon packed with the fecal accumulation of nearly four weeks' time. The sigmoid flexure was greatly distended, almost gangrenous, and tightly bound down by adhesions. Immediately below was felt a hard, nodular mass of irregular outline, occluding the lumen of the gut for about two inches. An inguinal colotomy was at once performed, and the gut irrigated with warm, sterilized water, through the artificial anus. Great quantities of fecal matter came away, but it was impossible to dislodge the masses in the ascending colon.

The patient's condition demanded a speedy termination of the operation, but it was found that the coils of intestine could not be returned to the abdominal cavity, on account of the extreme distention. Incisions were accordingly made in them, and subsequently closed with Lembert sutures. The abdominal cavity was then washed out with moderately hot sterilized water, the intestines returned, the wound closed, and a dressing applied. A rubber tube of large lumen was wrapped in sterile gauze and inserted in the artificial anus. A voluminous pad of antiseptic gauze was placed over this opening to catch all discharges. During the operation active stimulation was necessary. The patient was then put to bed, but succumbed in four hours.

An autopsy was held, and the rectal tumor removed for pathological examination.

To Dr. George Dock of Ann Arbor we are greatly indebted for the following report:

"*Dear Dr. Warden:* Your specimen from the rectum (hardened in Müller's fluid and alcohol) consists of a section of the intestine, with part of its attachment. The ends appear normal. The middle part is hard, of the same diameter as the ends, strongly curved, and measuring 8.2 cm. in length on the convex side. The peritoneal surface is smooth for the greater part, but in one place rough, as if the seat of inflammation. Cross-sections show an annular new growth, causing marked thickening of the submucosa. In some parts, the mucosa and muscularis are very narrow. The new growth also in-

vades the mesentery in some places. The thickness of the intestinal wall varies from 5 to 10 mm. The lumen is much contracted, measuring in most places involved by the growth between 4 and 8 mm. in diameter, in some parts being almost totally occluded.

"Sections cut from various parts were stained in various ways. Both in the involved and apparently normal parts the staining is imperfect. In the apparently normal parts the mucosa shows extensive small-cell infiltration, with excessive mucous degeneration of the tubular epithelium. In the involved parts, the mucosa shows extensive infiltration, sometimes appearing as granulation tissue, with remains of tubules. There are extensive areas of degeneration, with sloughing, reaching almost to the submucosa. In many places the muscularis mucosæ is absent, the granulation tissue and remains of the tubules being immediately above the new growth. This latter is alveolar, with narrow septa, containing few nuclei and few and small blood-vessels. The roundish or irregular alveoli contain more or less degenerated cells. In a few places these are roundish or polygenal, with protoplasm, which stains well with eosin, and small, roundish nuclei. For the most part, however, the alveoli are filled with roundish masses of colloid material, in which nuclei can rarely be recognized. Other cells are occasionally encountered which are only partially degenerated, the protoplasm containing round granules of colloid material. The new growth extends into the circular muscular coat irregularly, and, entirely replacing the submucosa, is from 3 to 5 mm. wide. In some places the circular muscular coat contains isolated alveoli; in others, rows of colloid cells, or larger rows of small, round cells. These latter stain poorly, so that details of the nucleus cannot be made out well, but are probably polynuclear. Other masses of colloid cells occur in the longitudinal muscular coat and beneath the serosa, sometimes reaching a thickness in the latter of 4 to 5 mm.

"The specimen is one of colloid cancer of the rectum, with ulceration, and effectually obstructing the lumen of the gut at that part. It is interesting on account of the patient's age, cancer of the rectum being uncommon in early life. Yours very truly,

George Dock."

REPORT OF TWO CASES OF SURGERY OF THE BILE PASSAGES WITH COMMENTS.[1]

By SCHUYLER C. GRAVES, M.D.,
of Grand Rapids, Mich.;
Consulting Surgeon to the U. B. A. Hospital and Surgeon to the Children's Home.

When one undertakes the discussion of the surgery of the bile ducts he must needs realize the limitations by which he is surrounded, for few as yet have had a very extended experience in this department. Although work along this line, as in other branches of surgery has, after a fashion, been done for many years, really modern procedures having been recommended by Petit as long ago as 1733, it nevertheless can be said that in this work we are touching upon a phase of the newer surgery. Especially is this true in its bearing upon the surgery of the common duct.

The surgery of the gall-bladder and ducts has lately undergone much scientific evolution, as the result of which many sufferers are restored to health and usefulness who hitherto have been abandoned to lives of torture and to lingering deaths. Those who have endured the pangs of biliary colic or who have witnessed the distress of others afflicted with temporary or permanent obstruction to the out-flow of bile, can realize the value of the hopes made possible by the development of an ever beneficent art.

Case I.—Mrs. M., aged thirty-two, weight 140 pounds. Since childhood patient has suffered from attacks of biliary colic. These occurred at intervals, varying from several days to several years. Early history of jaundice, but none since she was ten years of age. Agonizing epigastric and occasionally *left* hypochondriac pain, with chill, fever, and sweat, generally following a meal, and always, of late, following a heavy meal. Attacks recently very frequent. Marked dysmenorrhea, the biliary pain often following that of the former. (Having been considered by several physicians as a reflex of the altered menstrual *molimen* uterine dilatation was done with no effect upon the epigastric distress). Gall-stones were never noticed and true condition was unsuspected. A diagnosis: Ordinary cholelithiasis with periodical expulsion of calculi was made.

On July 3, 1895, at the U. B. A. Hospital, Grand Rapids, a right-angled incision (right hypochondriac region and linea semilunaris) was made, the gall-bladder located and found to contain stones. None were discoverable in cystic or common ducts. Viscus was stitched to parietal peritoneum with fine, aseptic silk, and wound closed with worm-gut sutures, except directly over fundus, which portion was packed with iodo-gauze and patient put to bed. Operation was difficult because of an excessive amount of adipose, the top of stitched bladder lying at least two inches below level of integument. Five days later (July 8th), without anesthesia, the organ was incised and twenty-one calculi, the size of beechnuts, removed by means of a dull, uterine curette. Cavity explored with finger and washed out, but no more stones found. Bile was dark, thick, and stringy. Rubber drain placed in bladder and external wound repacked with gauze, Three days later (July 11th) a hemorrhage occurred. It was found that the bleeding came from the interior of the gall-bladder. Several large, black clots were gently curetted away, but bleeding becoming quite brisk, both cavity and wound were packed with gauze. This tamponade controlled the flow sufficiently to prevent alarming symptoms, but the withdrawal of the gauze was invaribly followed by a recurrence of the hemorrhage. Finally the abdominal wound alone was packed, leaving the gall-bladder to fill with blood in the hope that coagulation would correct matters. This idea proved a happy one and there was no further bleeding to any extent, although the stools for several days were very black and tarry. This indicated escape of blood from the gall-bladder into the bowel, and was also the sign of patentcy in the cystic duct and the ductus communic choledochus.

[1] Read before the Barry and Eaton County Medical Society at Nashville, Mich., April 30, 1896.

No other bad symptom developed in the case; highest pulse-rate was 120 (second day); highest temperature 100.2° (eleventh day). Case left hospital on the 20th day, and fistula closed on the 34th. Patient has been in excellent health ever since, has gained forty pounds in weight, has no pain, does her own housework, and, strange to say, has very little, if any, menstrual distress.

CASE II.—Mrs. J. D., aged fifty-eight, weight 120 pounds. For many years patient has been a victim of "gall-stone colic". Had passed many calculi to her knowledge. At first no jaundice was connected with the attacks, then slight and transient pigmentation, and for the past few years the coloration has been permanent, although varying somewhat in intensity. When seen by the writer her skin and conjunctivæ were of a deep saffron color. Her sufferings were intense and paroxysms very frequent. Stools were of a clay color. Obstruction to the common bile duct, probably from the impaction of a large biliary calculus was the diagnosis made.

She was kept under observation for a week prior to operation. During this time she had a typical attack, pulse 120, temperature 103.2°. Sweating and evidence of pain were very marked, paroxysm lasting about two days.

September 24, 1895. Incision made as in Case I, and search instituted for the gall-bladder. This organ could not be found, and finger was passed to the region of common duct. Here a mass, seemingly the size of an English walnut, was readily discovered near the entrance of the duct into the duodenum. An exploring needle was passed into the tumor and found to pass with some resistance, but quite readily. This indicated carcinoma, but the circumscribed and movable character of the lump sustained the diagnosis of stone. The tissues intervening between the finger and the mass were incised, and touch immediately detected the presence of a large calculus. Wound very deep and partially filled with blood, hence sight was of no avail. The calculus, after considerable manipulation was turned out, and proved to be about the size of a robin's egg. Finger reinserted into the caliber of the duct, and a row of calculi, extending upward toward the liver, discovered. They were taken away as rapidly as possible and numbered over thirty, one being about one-fourth the size of the large one.

The finger readily explored the common duct on both proximal and distal sides, the confluence of the cystic with the hepatic duct being quite noticeable, the cystic duct, however, was extremely attenuated, while the hepatic was much enlarged, being, in fact, a reservoir for stones. It was very capacious and permitted easy digital exploration. A probe was passed into the duodenum and all obstruction found removed. No attempt at deep stitching was done, as the operation had consumed over an hour's time, in consequence of the difficulties naturally connected with the procedure. A glass drain was inserted in the duct and surrounded with iodo-gauze, made to project from the abdominal incision. A counter-opening also was made in accordance with a suggestion offered and discussed by Rutherford Morison,[1] who recommends draining such cases through "a pouch (lying) between the right lobe of the liver and the gall-bladder."

External wound closed with worm-gut sutures. Pulse ranged from 120 to 140 for two days. Temperature not high. Very deficient urinary secretion for first few days, but this was overcome by application of hot stupes to region of kidneys. Pulse came down to 112. Food was retained and relished. No tympanites. Abdomen soft and relatively free from tenderness. Bile drained nicely, golden-yellow in color. Gauze packing withdrawn on the third day and the glass drain removed on the sixth. On October 2d (eighth day), the pulse and temperature began to rise, the former in twenty-four hours reaching 160, and the latter 104°. Stupor developed. No apparent trouble with the drainage. No evidence of general peritonitis. Tube through counter-opening withdrawn and contiguous territory irrigated. No change for the better occurred, and patient died October 3d (ninth day).

The autopsy showed absence of general peritonitis, but much injection and some purulent exudate in neighborhood of the Morison pouch. The biliary drain-canal was completely shut off from the peritoneal cavity. A remarkable feature of the *post-mortem* was the inability of the pathologist to find even a trace of the gall-bladder. It had undergone inflammatory change to such an extend as to result in obliteration, the dilated hepatic duct, as noted by the finger, *ante-mortem*, having acted in the capacity of a vicarious reservoir. Seven more stones of ordinary size were found in the hepatic duct. The death of this woman, after such hopeful post-operative indications, was due, in my opinion, to ptomaine intoxication, from external infection through the counter-opening.

My comments are three in number and are brief:

1. Surgery offers hope of succor to many people who hitherto have suffered without thought of relief. Cholelithiasis is a common malady, in fact, very common, many persons being possessors of stones without their knowledge. These people are walking unconsciously in the shadow of a real danger, which is liable to present itself at any time. When that danger does come, it may be met by surgical interference.

2. Action should be prompt, if the best results are to be expected. In cases like No. II., it is unwise to tarry, for while in this case death seemed to be due to causes disconnected with the question of early or late interference, who can state that the low ebb in the patient's health and strength did not contribute in a material way to the demise? That beautiful theory of Metschnikoff, phagocytosis, may have had more to do with the unfortunate outcome in this case than we know. Surely an agency which depresses general health would diminish cellular resistance to microbic invasion as well, and thus assist in the destruction of life. At any rate, deathbed operations are to be discountenanced.

2. The rational treatment of cases like the foregoing, as in any case of surgery, consists in the removal of the cause, and that as speedily and safely as possible. The use of the Murphy button was not indicated in either of these cases, for while its employment in the first case might have been followed by the passive discharge of the

[1] "On Gall-stones." *Annals of Surgery*, vol. xxii, page 181. (August, 1895).

calculi through the intestinal fistula, it can not be denied that such happy result might possibly *not* have obtained. At any rate, the taking away of these stones was better than trusting that they might be washed away, as much better, in fact, other things being equal, as activity is better than passivity. But in cases like the second, viz.: ductus communis impaction, the button could not possibly work a cure, for the stone would remain to cause more or less future trouble.

In conclusion, I would state that in my opinion the employment of the Murphy button as a remedial measure in disorders of the biliary passages, should be limited to cases of permanent, non-lithic obstruction of the ductus communis choledochus, except where both bladder and common duct are stone-laden and the danger of the double operation necessary for relief is considered greater than the liability of future difficulty after its use.

A LABORATORY STUDY.

LIQUID PEPTONOIDS.

By ALBERT R. LEEDS, Ph.D.,
of Hoboken, N. J.;
Public Analyst of New Jersey.

In The Medical News of December 21, 1895, there is an article with the above title, by Dr. A. L. Benedict.

I desire to add the following observations to those made by Dr. Benedict, and confirmed in a posteript by Dr. Leffman, in relation to the small quantities of proteids exhibited by this preparation.

In connection with the reports upon the foods of infants and invalids, which I have made to the State Dairy Commissioner during years past, I have repeatedly examined the Liquid Peptonoids and have published its composition, stating not only the presence of proteids, but their percentage amount.

Since seeing Dr. Benedict's article I have obtained original packages of the Liquid Peptonoids, and subjected it to qualitative tests as well as quantitative analysis.

Dr. Benedict's observations on the character of Liquid Peptonoids are based practically on qualitative tests, and these tests were applied directly to the samples experimented on.

Inasmuch as my previous analyses had shown that the Liquid Peptonoids is composed of a number of substances besides proteids, and these substances many times larger in quantity, might interfere with the reaction for proteids as usually applied, I adopted the following procedure: The alcohol, which makes up a fifth of the bulk of the preparation, was distilled off, and the aqueous solution remaining behind was submitted to the tests. As it was strongly acid, there was reason to suspect that the precipitation of albuminates would be prevented by their solubility in an acid solution, and this was found to be the case. But by cautious addition of the Ritthausen solution of copper sulphate, in amount sufficient to precipitate only a fraction of the albuminates present, followed by the Ritthausen solution of potash, a flocculent precipitate of albumin containing some gelatin was obtained. After filtering off this precipitate, the Biuret test was applied in the usual manner and gave the rose color characteristic of peptone. The addition of concentrated sulphuric acid developed a deep claret-red color. Mercuric chlorid, phosphomolybdic acid, and tannic acid, gave abundant white precipitates. In order to demonstrate qualitatively the presence of gelatin in the filtrate, it was concentrated by evaporation, and while still hot, solid crystalized ammonium sulphate was added to saturation and then the sulphate was just re-dissolved by boiling water. An abundant sticky precipitate of gelatin was thus thrown down and attached itself to the sides of the evaporating dish and rod used in stirring.

Quantitative analyses gave the following results:

Alcohol by weight	15.99 per cent.
" " volume	19.68 "
Albumin	0.182 per cent.
Gelatin	0.262 "
Peptone	0.377 "
Total proteids	0.821 per cent.
Maltose	4.735 per cent.
Sucrose and lactose	5.16 "
Total carbohydrates	9.895 per cent.
Hydrochloric acid	0.034 "
Ash	0.205 "
Total solids	10.921

So it appears plainly that the reasons for the negative results of Dr. Benedict's tests for proteids was due to the very dilute solution of the proteids in association with the other bodies, the proteids actually forming less than one-tenth of the whole solid content.

Liquid Peptonoids is stated to contain the albuminoid principles of beef, milk, and wheat, entirely digested and ready for assimilation. So, in the light of this statement and of the name itself, it is not unreasonable to expect such Liquid Peptonoid to contain a preponderance of albuminoids in its constituents. Ordinary market milk contains, on an average, 3.75 per cent. of albuminoids, of which 0.75 per cent. is non-coagulable albumin and peptone. Should not a preparation of predigested milk contain considerably more than 0.75 per cent. of albumin and peptone? Here we have a preparation of predigested *beef*, *milk*, and *glutin*, with only 0.821 per cent. of proteid matter.

In the analyses previously published[1] I found over two per cent. of proteids, and other published analyses, one, I think, by Dr. Chittenden, stated two and a half per cent.

It is evident, therefore, that the present preparation is far below the standard of the original, containing only about one-third of its original proportion of albuminoids.

In the State Report, the objection was made to this preparation that it contained too small a percentage of albuminoids to justify the claims that were made in its behalf. The present composition, as disclosed by this analysis, only the more strongly sustains this criticism.

I believe that peptone has a peculiar value in nutrition; may be of incalculable value as compared to food in its ordinary form, and so, even in small quantities, of the greatest benefit to the sick. But however high the factor of peptone may be as a nutrient, a preparation advertised

[1] See Report N. J. Dairy Commissioner for 1887.

to "contain the albuminoids of beef, milk, and glutin, in an entirely digested form," is seriously deceptive in its character when it contains but 0.821 per cent. of total proteids of all kinds, and is far below a reasonable and easily attainable standard.

I have been severely criticised, and frequently threatened with legal prosecution and large punitive damages, for publishing analyses of some infant and invalid foods, and for saying what appears to me to be the truth concerning these foods; but I am of the opinion, nevertheless, that these manufactured foods should be the concern of the various boards of health, with as great benefit to the public, no doubt, as in the regulation of the production and sale of beef, milk, etc.

MEDICAL PROGRESS.

Recovery from Focal Epilepsy Following Removal of Subdural Sarcoma.—Czerny (*Münchener medicinische Wochenschrift*, 1896, No. 11, p. 241) has reported the case of a stonemason, forty-one years old, who at the age of thirteen years was rendered unconscious by a blow upon the occiput with a stone. At the age of thirty-four years, severe headaches set in, followed soon by twitching at first in the left leg, and subsequently involving gradually the remainder of the left side. For a time the attacks were controlled by bromids, but subsequently they recurred with increased severity and involving also the left upper extremity and left side of the face. In addition to these minor attacks, the man had major ones, lasting for twenty minutes, in which consciousness was lost. Operation was at this time proposed, but not assented to. Upon coming under observation some eight months later, examination disclosed two fingers' breadth to the right of the median line, and a finger's breadth above the transverse sinus a non-adherent cicatrix of the scalp. There was no optic neuritis. Sensibility and motility were practically alike on both sides; there was, however, slight impairment of the muscular sense on the left. There was a sense of restlessness and a feeling of fear and formication upon the left side. The memory was impaired. While under observation, a severe convulsion occurred, beginning in the left leg, progressively extending to the left arm and the left side of the face, followed by general twitching of the whole body, tonic spasms and loss of consciousness for a quarter of an hour, followed by mental confusion. A diagnosis of cortical tumor of the brain was made and operation undertaken. A tongue-shape flap with its base toward the ear and its apex toward the median line was turned back from the right parietal bone in a situation corresponding to the upper extremity of the Rolandic fissure. The dura, which was dense and scarcely pulsated, was incised and a flap turned back. Corresponding to the upper extremity of the ascending parietal convolution, was a bluish-red, circumscribed, nodular tumor measuring 1¾ x 1½ x 1⅓ inches attached to the inner surface of the dura and to the falx. Anteriorly, extending forward to the ascending frontal convolution, was a cyst as large as a hazelnut filled with serum. The tumor was only slightly attached to the brain, posteriorly, and was easily dissected away, with little hemorrhage. Following the operation, tonic spasm and twitching appeared in the extremities of the left side, and for a time the patient was extremely irritable; but in the course of a month the wound had almost healed and the patient was able to get out of bed. A slight suppurating fistule remained for a time. Six or seven weeks after the operation, a further convulsion occurred, which was not repeated, however, after the evacuation from the wound of a small accumulation of pus. Upon histologic examination, the tumor proved to be a spindle-cell sarcoma arising from the dura.

Paroxysmal Laughing Spasm.—At a recent meeting of the Psychiatric and Neurological Society of Vienna, Infeld (*Wiener klinische Wochenschrift*, 1896, No. 10, p. 179) presented a man, thirty years old, who for three years had been having attacks of laughing spasm. These occurred at first at intervals of two or three months, gradually increasing in frequency to sixteen in the day. Some diminution followed treatment with bromid, which, however, was suspended as the attacks again increased in frequency, and the patient's memory began to suffer. The attacks occurred especially between nine in the evening and half-past six in the morning, and in greatest frequency between five and half-past six. Some occurred also during the day, however the patient happened to be occupied. In the intervals between the attacks, and immediately before and afterward, the man was perfectly well. The attacks set in with a sense of formication arising from the toes of the left foot, and the patient would fall to the ground unless he could reach some place to lie down. When this feeling reached the level of the left nipple the patient lost consciousness briefly, for two seconds, he estimated. Then followed tonic spasm, beginning in the lower extremities with strong dorsal flexion of the foot and toes, and successively extension at the knee, slight flexion of the thigh, at times deflection of the head to the right, slight adduction and abduction of the arms, flexion and pronation and supination of the forearm and the hand, flexion at the wrist, and extension of the fingers. The spasm was less pronounced on the right than in the left. Often the patient lay upon his face. The mouth and eyes were closed spasmodically, the eyeballs turned upward; the pupils were dilated and unresponsive to light. At the height of the attack the patient at first smiled, and then laughed aloud without other sign of merriment. The entire attack occupied about two minutes. On two occasions there was protracted loss of consciousness. The patient had suffered numerous injuries from falls, and his tongue presented several scars. Sometimes the sensory phenomena appeared without the motor, and several times it was possible to abort the attack by construction of the left arm with a ligature. Improvement followed the administration of potassium bromid, in doses gradually increased from 90 to 225 grains daily. At the age of fifteen years the patient had suffered injury of several fingers, of the right thigh, and of the right side of the face. He had for a year or more, several years before his attacks began, indulged in alcohol to excess, and had been much depressed by the death of his father. On one occasion he had tem-

porary loss of use of the right leg. The case was believed to be one of minor epilepsy.

Carcinoma of the Rectum in a Youth of Thirteen Years.—Czerny (*Münchener medicinische Wochenschrift*, 1896, No. 11, p. 241) has reported the case of youth, thirteen years old, who presented in the rectum, just below the promontory of the sacrum, a tongue-shaped tumor, attached posteriorly, and ulcerated upon its inner surface. A small piece removed presented the arrangement of a cylinder-cell proliferation, and on account of the age of the patient a tentative diagnosis of papillary adenoma was made. Radical operation was, however, advised. The tumor had been in process of development for six months. The rectum was resected for a distance of 2½ inches in conjunction with osteoplastic division of the fourth sacral vertebra. The carcinomatous ulceration involved the rectum for a distance of an inch and a half, and extended through the muscular into the serous coat. All of the involved structures were removed, but the circular suture of the intestine failed to hold securely, so that a small fecal fistula resulted.

Percussion of the Heart with the Body Bent Forward.—From a clinical study Gumprecht (*Deutsches Archiv für klinische Medicin*, B. lvi, H. 5, 6, p. 491) has found that the absolute cardiac dulness is increased in extent, intensity, and resistance, by inclining the body forward during the act of percussion. While this dulness often disappears in the dorsal decubitus as a result of pulmonary emphysema or gastro-intestinal tympanites, it is demonstrable when the body is inclined forward. With the aid of this procedure otherwise unrecognizable hypertrophies of the heart are rendered diagnosticable, and especially the left-sided hypertrophies of age masked by pulmonary emphysema—such as those associated with arterio-sclerosis or contracted kidney—and less commonly right-sided hypertrophies.

THERAPEUTIC NOTES.

In the Treatment of Membranous Dysmenorrhea.—Lyonais (*Médecine Moderne*, 1896, No. 25, p. 198) recommends the following plan of procedure: For the pain of the paroxysm the usual sedatives may be employed; of especial use are cannabis indica, sodium salicylate in doses of from 15 to 120 grains in twenty-four hours, enemata of camphor and opium, of chloral, suppositories of opium, antipyrin, etc. No remedy, however, equals the hypodermic injection of morphin hydrochlorate given in doses of ⅙ or ⅓ grain night and morning until the membrane is expelled. For two or three days preceding the menstrual period vaginal injections of hot water (118.4° F.) may be practised. In the intervals between menstruation, if the cervical canal is constricted the incision of Sims may be made, or dilatation attempted with bougies or laminaria tents. The uterine mucous membrane may require curetting or cauterization. Displacements of the uterus, fibroid and other tumors, will require appropriate treatment. If the adnexa be diseased their removal may be seriously considered. Sometimes the pain disappears spontaneously or as a result of conception when due to arrest of development of the uterus. Under these conditions benefit may result from hot foot-baths, vaginal injections at a temperature of 114.4° F. and emmenagogues. When a diathetic state coexists iodin in alcoholic solution with tannic acid, or with potassium iodid may be employed together with cod-liver oil, arsenic, alkalies, etc., especially in cases presenting lymphatism, scrofula, defects in development. In some cases hydrotherapy and electrotherapy prove serviceable.

The Antiseptic Action of Subnitrate of Bismuth.—The *British Medical Journal*, April 4th, quotes Carles in the *Archives Cliniques de Bordeaux*, February, as opposing the theory that subnitrate of bismuth has a merely mechanical action. Gayon and others have proved that it has a powerful bactericidal action, and the author found that an easily decomposable solution containing subnitrate of bismuth keeps indefinitely. Gosselin and Heret have found it useful for cleansing putrid wounds. To understand its action when given internally one must remember that the purest specimen tends to split up into bismuth oxid and nitric acid when in contact with water. (1) Action on the stomach. The oxid, which is in excess of the acid, acts first as a detergent to the gastric mucous membrane and precipitates the mucus, and, secondly, by its special germicidal power. The nitric acid has a tonic astringent and also a special antiseptic action (Duclaux). (2) In the intestine it meets with sulphureted hydrogen gas, which converts it into black sulphid, thus liberating a further portion of its acid, which is again partially transformed into nitrous vapors, the antiseptic action of which has been proved by Girard and Pabst. For these reactions to take place it is necessary (1) that the subnitrate should be pure and not mixed with carbonate; (2) that it should be as finely powdered as possible. This latter point is easily proved in the laboratory. Thus it is not necessary to give up this old remedy for the newer, the salicylate, which costs twice as much.

The Treatment of Diffuse Bronchitis in Infants by Means of Warm Baths.—At a recent meeting of the Académie de Médecine Renant, (*Médecine Moderne*, 1896, No. 25, p. 198) recommended in the treatment in diffuse bronchitis in children systematic bathing, every three hours, in water at a temperature of 100.4° F. for seven or eight minutes, if the bodily temperature reaches 102.2° F. or more. As a result, as observed in more than a hundred cases, the fever soon declines and the bronchitis yields. Quinin sulphate or hydrobromate was employed in tonic doses as an adjuvant. In cases of capillary bronchitis, in which the temperature rises high (104 –105.8° F.), the temperature of the bath may be reduced to 95° or 96.8° F.

For the Pain of Gastric Ulceration.—

℞	Exalgin		45 grains.
	Extract of belladonna, Codein, phosphate.	aa	5 grains.
	Sugar of Milk . . .		75 grains.

Mix and divide into ten cachets.

Dose, one to be taken with the onset of pain.

Boas.—*Semaine Méd.*, No. 18.

SATURDAY, MAY 30, 1896.

THE BROOKLYN JENNERIAN CENTENNIAL.

The celebration at Brooklyn on the 14th inst. was a "red letter" evening. The two distinguished invited medical guests, Drs. Pepper and Welch, did not fail of their promise to attend, and made addresses worthy of their standing and of the occasion. Dr. Pepper especially, was masterly in his presentation of the case in favor of vaccination, and, in part, said: "Too much attention cannot be paid by us to the worth of Jenner. Very few of us have the desirable amount of knowledge concerning Jenner's life as a man and an original investigator, and his immortal discovery. To him is due that extreme and rare credit of having devised the incalculably valuable scheme of close and patient observation, without which great discoveries in the realm of science are a hopeless dream.

"Jenner's discovery has removed a scourge from the face of the earth. But think how many others still await solution at our hands! Their solution depends upon the methods he put into such successful operation. I have taken the trouble to secure a few statistics of preventable deaths in Philadelphia for the past twenty years. The result is startling. There were 55,000 deaths in that city alone in that time from tuberculosis, 11,500 from typhoid fever, 8000 from scarlet fever, and 155,000 from various infantile causes, all of which must be included in the list of preventive diseases. If we should personally practise preventive medicine, I am certain our services would be vastly greater to suffering humanity than ever before. It is a higher medicine than that which seeks to quell contagious disease after it has spread over our cities and eaten into the vitals of the people. This is a very serious matter and needs deep thought. We ought to get it planted in our schools and public libraries.

"Municipal and national preventive medicine is also our great need. How much do municipalities appreciate this? How many laboratories do our cities endow? I tell you, that to-day the medical profession is the only profession which is trying forever to restrict its own field of effort and emolument. Yet, when it tries to secure government or city cooperation, it is set upon as if it were trying only to secure personal gain. We should unite in insisting upon the immense importance of these subjects—health, the prevention of disease, and epidemic. Here, in this aggregation of population, soon destined to be the second greatest city in the world, is a magnificent opportunity. Let it lead in showing the world its zeal for the succor of humanity. This is, moreover, a national question. Cities cannot deal largely enough with questions of quarantine, the pollution of the sources of water, the pollution of our coast waters and the poisoning thereby of our sea food product. Then there are the great domestic food crops and our food animals. I do not want more centralization in Washington, but modern preventive medicine demands national control. We must speak strongly for humanity and demand recognition for these things. Remember that our duty is to force this question into immediate public recognition."

Dr. Welch chose for his subject the scientific bearings of Jenner's discovery, and its logical consequences in the development of preventive medicine. He characterized the discoverer of vaccine as a thoroughly trained scientific man. "He knew pathology, and knew it well. His inves-

tigations were entirely of a scientific character, and no man in medicine has been less selfish in his his work. Jenner was the first physician to make a *post-mortem* examination in the case of angina pectoris, and the discovery of its nature was really due to him. His careful investigation convinced him of the accuracy of his opinion that it was merely an ossification of the coronary arteries. That little monograph of Jenner's on vaccination is one of the classics of the language. It takes rank with Harvey's essay on the heart. It illustrates perfectly his far-reaching, painstaking observation, and his careful study of every aspect of this subject. Dr. Pasteur, whose great discoveries in our own time have electrified the medical world, gives full credit to Jenner as the source of his inspiration. The theory of preventive medicine is to-day a principle as likely to be as beneficent to humanity as that discovered by Jenner. All of our great discoveries rest on the application of experimental method in medicine. They rest on experimentation on animals; vivisection, if you like it. But it is a necessity. There has never been a time in which great discoveries in medical science have been possible, except through the agency of experimentation. Your society has shown an enlightened spirit in recognizing this opportunity to honor the memory of Jenner, and I thank you for the privilege that you have extended to me to participate in doing honor to his memory."

The memorial medal, given to each guest, is of bronze, and fitly commemorates the occasion. The menu of the banquet quotes Scriptural text as applicable to the great sanitary pioneer: "He stood between the living and the dead, and the plague was stayed."

TUBERCULOSIS OF THE KIDNEY.

There is increasing evidence that tuberculosis of the kidney, both primary and secondary, is commoner than the frequency of its recognition heretofore would lead one to believe. The importance of early detection, particularly if the lesson is primary or localized, must be obvious, as a number of recent observations have demonstrated the possibility of perfect recovery as a result of radical surgical intervention. The diagnosis depends essentially upon the detection of tubercle-bacilli in the urine, obtained, if possible, directly from the ureter of the diseased organ. The early symptoms may fail entirely to attract attention. As the case progresses these are likely to assume the characters of those due to inflammatory lesions involving the part affected. The most conspicuous manifestations ordinarily are pain in the loins, often paroxysmal in character, and much like that of renal colic, together with the passage with the urine of blood and the *debris* of disintegrated tissue. Ultimately, constitutional symptoms appear, perhaps with evidences of extension, and often late in the progress of the case a swelling in the loin may be detected on palpation. When the affection, especially if primary or localized, can be recognized the remedy lies in resort to surgical measures, and in accordance with the conditions present these will consist principally in nephrectomy or nephrotomy. In a recent communication emanating from the Pepper Laboratory of Clinical Medicine, Hamill[1] considers this subject in its various clinical aspects and reports fifty-five cases that he has collected from the literature. Operation was performed in seventeen of this number, with the following results:

	Cases	Improvement	Recovery	Death
Nephrotomy...	4	1	2	1
Nephrectomy..	9	1	5	3
Nephrotomy followed by nephrectomy...	4	1	2	1

These results must be viewed as in the highest degree assuring and should stimulate the clinician to an early diagnosis.

An additional case illustrating the success attending early recognition and radical treatment of tuberculosis of the kidney has recently been reported by Casper (Berliner klinische Wochenschrift, 1896, No. 17, p. 369). The patient was a woman, forty-two years old, without hereditary predisposition, who for six months had complained of symptoms of vesical catarrh, to which became added pains in the right loin, together with a sense of abdominal tension. Varied local treatment proved unsuccessful. The urine was

[1] "Primary Tuberculosis of the Kidney, with Especial Reference to Its Manifestations in Infants and Children," p. 35. Philadelphia, 1896.

slightly turbid and of acid reaction with a specific gravity of 1018. It contained numerous pus-corpuscles and ciliated epithelium, but neither blood-corpuscles nor tube-casts. A small quantity of albumin also was present. In the centrifugated sediment tubercle-bacilli were found. Upon cystoscopic examination the interior of the bladder appeared normal except in the situation of the right ureter, whose opening could not be seen. In its usual site was a diffusely reddened elevated area in which blood-vessels could not be recognized. The urine from the left ureter appeared clear and normal, while none could be seen to issue from the place where the right ought to have been, although from time to time a few drops collected in this situation. The left ureter was readily catheterized with the aid of the ureter-ocystoscope and the urine obtained proved to be normal. After a number of unsuccessful attempts to enter the right ureter the catheter disappeared beneath the mucous membrane of the bladder and was readily pushed further onward. The urine thus obtained resembled that found in the bladder, being turbid, purulent, and albuminous. Upon the first examination tubercle-bacilli could not be found, but at a subsequent examination their presence was conclusively demonstrated. A diagnosis was therefore made of tuberculosis of the right kidney, with circumscribed involvement of the bladder. Accordingly nephrectomy was performed, with the recovery of the patient. The removed kidney presented tubercles upon its surface and two caseous nodules in its parenchyma.

THE INCREASING LACK OF ESPRIT DE CORPS IN THE MEDICAL PROFESSION.

It must be apparent to any thoughtful mind that the medical profession is fast drifting away from its ancient ethical standards. In some respects this is well, for those standards were instituted when the conditions of social life were far different from those which now obtain. Because of the supposed greater intellectual attainments which belonged to a certain decorum and dignity formerly inhered in them all the so-called learned professions when compared with the trades and handicrafts. Such a system fostered shams, it is true, and placed many men before the community at more than their real value. The medical profession was not peculiar in this respect, for quacks and sharpers and hypocrites were to be found in the other learned professions also. Furthermore, the rigid ideas of the earlier days helped to keep within conventional lines some who might otherwise have gone astray, and these ideas were not regarded as burdensome by those who had no disposition to wander.

When the general average of intelligence was advanced, when greater tolerance for differences of opinion prevailed, and when the law of the commonwealth established one standard of requirement for all who engaged in the practice of medicine, allowing latitude of opinion in matters non-essential, the era of greater liberty of action was ushered in. We do not as yet fully realize the advantages of such a situation. With the era of greater liberty has come a distinct lowering of ethical standards in the reciprocal relations which physicians hold to each other, a tendency to regard the art medical as not much more than a trade, a means of obtaining a livelihood, a means of making money. If the art medical is all of these, which is quite true within certain limits and with certain individuals, it is also much more than these. It is indeed the means by which physcians gain their livelihood, support their families, and make provision, in the rare instances in which it is possible, for old age; but it is no better than the dirtiest and most slavish kind of a trade, if instead of developing character and making one broad and humane, it debases one into a mere money-getter, a sordid, avaricious seeker for selfish advancement with no generous thoughts or impulses for others who are working in the same field. It is deplorable that there are physicians in this city, not to mention a like possibility in other communities, who, if reports are to be believed, not only expect but demand fees for services rendered to fellow-physicians or those who are immediately dependent upon them. A sense of gratitude and propriety should certainly inspire those who are able to make compensation for conspicuous services rendered. Only a small-souled or an excusably impecunious man would be unmindful of such an obligation, but even then the requital should come only as an expression of gratitude, never as a fee which was required.

It is time that the profession showed greater solidarity in these matters. It is time that the mere money-getters be allowed to be isolated from those who believe that the cultivation of fellow-feeling, broad charity, and generous impulses within the profession should not be allowed to degenerate into a lost art.

ECHOES AND NEWS.

The principal Medical Libraries of New York City consist of the N. Y. Hospital Library, 25,000 volumes, the Library of the Academy of Medicine, 45,000 volumes, and 15,000 volumes devoted to medicine in the Mercantile Library.

The Faculty of the New York Polyclinic Medical School and Hospital has appointed Dr. W. W. Van Valzah Professor of General Medicine and Diseases of the Digestive System and the Blood. Dr. J. Douglas Nisbet has been appointed Adjunct Professor to the same chair.

In 1888, W. E. Smith invented the drop-frame bicycle and built one for his wife. Mrs. Smith's first wheel weighed sixty pounds. She herself tipped the scales at eighty. Since then she has gained forty pounds, and her wheel has lost exactly the same amount—which says a great deal for the evolution of both women and bicycles.

One hundred years ago, May 14, 1796, Dr. Jenner first performed the operation of vaccination in England. The civilized world recognizes this as the greatest discovery in preventive medicine of all time. And yet in England to-day there is raging at Gloucester a most virulent epidemic of smallpox. What a commentary it is that the perverse folly of a small but noisy band of faddists has been able to bring such a scourge upon a large and prosperous community.

The Milwaukee contention over vaccination in the public schools has happily been placated. The suit of John Schierl against the School Board has been withdrawn from the Supreme Court; no costs to either side. The School Board will be free hereafter to enforce the rule requiring that every pupil shall give evidence of a successful vaccination before admission to the public school.

The Medical Society of Westchester County, N. Y., celebrated its one-hundredth annual meeting on the 20th instant.

It is estimated that from eight to twelve millions of dollars will be saved the United States Treasury annually by repealing the measure relating to free alcohol for the arts and sciences.

Professor Lombroso has expressed his belief that Dante was insane, and that the visions depicted in his "Inferno" are those from a disordered brain and should not be considered emanations of genius.

The serious illness of Sir J. Russell Reynolds of London, is almost as deeply regretted by the medical profession in America as in England. It will be learned with pleasure by his many admirers here that his symptoms are more favorable and hope is now entertained of his early recovery.

It is stated that the prime cause of the recent fatal illness of Archduke Karl Ludwig of Austria, brother of the emperor, was found in the water of the river Jordan, which he drank as a matter of religious devotion.

The profession is gradually purging itself of quacks and mountebanks. An Italian, Cacciola by name, has been arrested for practising medicine in Brooklyn without a diploma or certificate of registration, and the Pennsylvania State Medical Society has succeeded in convicting a notorious female quack in Pittsburg on a similar charge.

The British Association for the Advancement of Science will hold its meetings this year at Toronto, Can., commencing August 18th. The last meeting in Canada was in 1884, at Montreal.

It is rumored that the British army authorities are about to make a number of concessions to the members of the medical staff. The English medical journals are inclined to look with suspicion upon these promises, and point to an established disposition on the part of these authorities to forget them as soon as the ranks are well filled from the applicants they have attracted.

Dr. Charles F. Chandler, Professor of Chemistry in the Columbia School of Mines, New York, has completely recovered from an attack of appendicitis, which prostrated him six weeks ago. The attack came without warning. He arose in his usual health, but before noon was seized with severe pains, which were diagnosed at a consultation of physicians a few hours later as those of appendicitis. The next morning the diseased appendix was removed. Apparently at no time after the operation was he in danger, while the operation seemed necessary to save his life.

A dispatch from Cairo, Egypt, says that a cholera miasm, similar to that of 1883, overhangs the city. It is accompanied by a heavy, hot atmosphere. The virulent form of the disease has hardly ever been paralleled at such an early stage. The deaths are about ninety per cent. of the seizures.

Moritz Pront, the nineteen-year-old boy who has been in a cataleptic trance since April 27th, remains in his strange condition at the Beth Israel Hospital in East Broadway, New York City. The starvation treatment, so-called, has been stopped, and the boy is being fed again artificially at regular intervals. He is apparently very feeble but the prognosis is favorable.

On May 22d a memorial meeting under the auspices of the Montgomery County Medical Society was held in the Court House at Norristown, Pa., as an expression of respect for the late Dr. Hiram Corson. Speakers were present from Philadelphia, and much feeling was displayed in honoring the memory of one whose worthy life had endeared him to the noblest of his fellow-men.

Drs. Henry W. Cattell and Thomas J. Morton have been appointed coroner's physicians for Philadelphia to succeed Dr. William K. Mattern, deceased, and Dr. H. L. Sidebotham, resigned.

It has been determined by a Russian bacteriologist that coffee is, to a limited degree, a disinfectant. This quality is not dependent upon the active principle of the bean, but develops in some manner during the process of roasting. Watery infusions of the roasted coffee prove fatal to the cholera bacillus in a few hours, and after a longer time the typhoid fever germ also succumbs. This germicidal effect is much too slow to render this discovery of any real therapeutic value.

A very timely warning is given in *Médecine Moderne* regarding the popular use of extracts of Kola. This article is entitled "The Kola Delusion," and in its discussion the fact is pointed out that increased capacity for work obtained through its employment is temporary and unreliable, like that gained from alcohol and cocain. In truth, the effect produced by every member of this group of drugs, which the author very aptly calls "nerve-foolers," in that they abolish the natural sense of weariness and fatigue, is due probably to an obtunding effect upon the nerve centers. That caffein is closely allied to creatin and other tissue poisons which invariably give rise to a loss of energy when they have accumulated in the body, is a further suggestive observation.

The Sisters of Mercy have nearly completed their retreat for consumptives in the Adirondacks. It is located upon a large tract of land presented to them by Dr. W. Seward Webb and Mr. Paul Smith, and is the choice site in the immense estates of these gentlemen. "Sunrise Mount," as it has been named, is two thousand feet above the sea, and surrounded by miles of pine forests and scenery unsurpassed. The cottage system is adopted. A most important advantage possessed by this sanitarium is accessibility. It may be reached without change of cars from most of the Eastern cities.

The St. Louis Board of Health made public the results of a trial of antitoxin in 326 cases of diphtheria. Of this number, only 15 cases died, showing a percentage of mortality of 4.6. Both the city of St. Louis and the promoters of antitoxin therapy are to be congratulated upon these excellent results.

Promising indications of establishing a hospital in the southern part of Brooklyn are found in recent meetings held by the influential citizens of that district. The larger hospitals of Brooklyn are much too remote to render prompt assistance to the poor of this populous region.

The Pennsylvania Board of Health has been clothed with power the exercise of which does not meet the approval of certain of the Philadelphia clergy. An act passed June 18, 1895, made it obligatory, under penalty of the usual fine, upon those in charge of all public, private, parochial, Sunday, or other schools to cause the children in attendance to present certificates of vaccination and to exclude and report such as were unable to furnish the same. The application of this and other sanitary requirements to Sunday schools is thought by those in charge to be unnecessarily burdensome.

The Pennsylvania State Medical Society held its forty-sixth annual meeting at Harrisburg, last week. The session was well attended, and its interesting program scientifically and harmoniously carried out. Dr. E. E. Montgomery of Philadelphia was elected president for the ensuing year. The next meeting will be held in Pittsburg in September, 1897.

Carl Pennington Frost, M.D., LL.D., Dean of the Dartmouth Medical College and Professor of the Science and Practice of Medicine, died May 24th, at Hanover, N. H., of heart disease. He caught a bad cold last spring, and has not been able to be out except for short drives since then. He received the degree of A.B. from Dartmouth in 1852, A.M. in 1855, graduated from Dartmouth Medical College in 1857, and received the degree of M.D. from New York Medical College in 1859. Dr. Frost leaves a wife and two sons, graduates of Dartmouth, class of 1886, the older, G. D. Frost, M.D., Professor of Anatomy in Dartmouth Medical College, and the younger, E. B. Frost, Assistant Professor of Astronomy in Dartmouth College.

CORRESPONDENCE.

SEASICKNESS—A REPLY TO DR. ROCKWELL'S ARTICLE IN THE "MEDICAL RECORD" OF JANUAY 25, 1896.

To the Editor of The Medical News:

Dear Sir: In reply to Dr. Rockwell's very efficient paper on the preventative treatment of "mal de mer," I would like to say a few words in defense of the ship's surgeon and give a few opinions as regards this most distressing malady.

The ship's surgeon labors under great disadvantages as regards his opportunities to allay the suffering of seasick passengers. In the first place, he never sees any of the passengers until an hour or so before sailing, and then he has but little opportunity to give any preventive whatsoever. Another difficulty is that many of the susceptible passengers become nauseated immediately they come on board, and cannot retain anything on the stomachs. Here is where hypodermatic medication comes in very opportunely. An injection of one-quarter grain of morphia, combined with 1–100 of atropin, scarcely ever fails to relieve the patient after one repetition. The nausea is allayed almost immediately. I have tried it, not only in seasickness, but in the nausea caused by railway travel, and have every reason to believe that, if used in time, it will always prove to be efficient.

Seasickness is undoubtedly due to a disturbance of the central nervous system, caused by a partial paralysis of the vasomotor nerves. This paralysis causes a passive congestion of the brain, owing to the relaxed blood-paths, and produces the distressing dizziness, headache, and vomiting. To prove that the nausea is due to nervous irritation, the patient vomits with a clean tongue, unless

there is constipation present, when there may be a slight coating. What causes the primary nervous disturbance, we are unable to say. Whether it due to the odor of the ship, the sight of the heaving water, or to the rolling of the vessel, we are at a loss to know. I have seen persons seasick before we had left "yellow water" and before there was any swell at all. I have found that those who are of a so-called bilious temperament are much more liable to seasickness than persons who are of an opposite temperament.

I had tried the bromids before reading Dr. Rockwell's paper, several times, and found that they produced the desired effect. Chloral will also prove to be a good prophylactic. Patients for whom I have prescribed the above drugs have told me that they were not troubled in the least during the voyage by seasickness. Given in fifteen-grain doses, three times a day, for two or three days before sailing, will be found enough to produce the desired effect.

Knowing that there is a relaxed condition of the blood-paths and a nervous excitability, it stands to reason that the use of morphia for the nervousness and of atropia for a vasomotor stimulant are the proper therapeutic indications.

In closing, I would remark that, aside from seasickness, there is another condition to be combated by the ship's surgeon, which always occurs with "mal de mer," viz., obstinate constipation. Whether this is due to the inactivity among persons on shipboard or the seasickness, I cannot say. I know that it is sometimes a very difficult matter to make any ordinary purge given in usual doses to act, and very large doses have to be given. I have found the cascara sagrada, given in ℥ss doses, disguised by syrup of orange, at night, the most agreeable and efficient purge.

Charles S. Bowman, Surgeon.

On Board S.S. Illinois, Antwerp, Belgium.
April 1, 1896.

COLLECTIVE INVESTIGATION IN PNEUMONIA.

To the Editor of The Medical News:

Dear Sir: My two collective reports, already published, on "Ice-cold Applications in Acute Pneumonia," give a record of 195 cases so treated, with 7 deaths, or a mortality rate of 3.58 per cent.

Being desirous of making as full a report as possible on this subject, I take the liberty of asking those members of the medical profession who have tested this measure to kindly give me the result of their experience. Full credit will be given to each correspondent in the report which I hope to publish. Blanks for the report of cases will be furnished by me on application.

Thomas J. Mays, M.D.

1839 Spruce street, Philadelphia.
May 1, 1896.

NEW METHOD OF ADMINISTERING CALOMEL.

To the Editor of The Medical News:

Dear Sir: I have occasionally wished to administer a vigorous cathartic to one suffering with mania or other mental disease, when the medicine could not be given by mouth without a struggle. A simple and effective expedient in such cases is to blow calomel into the nostril through a tube or roll of paper. The patient may be blindfolded, or, better, led to shut the eyes tightly, to escape having the application made directly to them, for such deception is certainly justifiable in some cases. The drug is nicely distributed over the nasal tract, finds its way into the intestinal tract, and operates as if given by mouth. It is not painful nor disagreeable, as I have demonstrated by personal trial.

Because I have never seen this little expedient mentioned, I send you this note, for it is of great value in certain cases.

Yours very truly,

J. N. Hall, M.D.

Denver, Col.,
April 30, 1896.

EXPANSION AND CONTRACTION METHOD OF FILTRATION.

To the Editor of The Medical News:

Dear Sir: In a reprint from the *Boston Medical and Surgical Journal*, recently sent to me, dated April 25, 1895, I find that Dr. Louis F. Bishop of New York first applied the test-tube in the expansion and contraction method of filtration as given in his paper: "A Quick Method for the Filtration of a Small Quantity of Urine," which I considered original with me, as published in your issue of March 21, 1896.

A comparative study of the papers indicates that the fundamental principles of the theory are the same in both, yet in practical application mine is a simplification of his method. Yours truly,

Samuel H. Friend, M.D.

Milwaukee, Wis.,
May 8, 1896.

COLORED MEDICAL DOCTORS AS ATTENDANTS IN INSANE ASYLUMS.

To the Editor of The Medical News:

Dear Doctor: In the April 4th number of the Medical News in the "Echoes and News" column, page 387, there appears this statement: "Governor Bradley of Kentucky, has appointed Dr. B. F. Porter (colored), third assistant physician to the Lakeland Asylum. As he will have several wards containing white patients under his medical supervision, the governor has been receiving rather unpleasant criticisms throughout the State." I have seen no such criticism in the press of this State, although you doubtless have. I beg to call your attention to the fact, that the statement whatever its source, is absolutely untrue, and ask that you will kindly correct the error. Dr. Porter, an intelligent and reputable colored doctor, is the third assistant physician in this asylum, appointed by Governor Bradley. He was appointed to take charge of the colored patients, of whom there are over two hundred in this institution. He has never had charge of a white ward or white patient since he has been on service. His work and duties are exclusively with the colored patients, are entirely satisfactory, and his presence has not produced the slightest friction in the management and con-

duct of the affairs of this institution. I think it has come to be regarded as not an improper appointment, and really now is looked upon as a very correct and suitable arrangement to have a colored doctor to look after the interests of the colored patients, which he does with great zeal.

Very respectfully,

H. F. McNARY, Superintendent.

LAKELAND, KY., May 19, 1896.

[THE MEDICAL NEWS is gratified to know that the original statement is incorrect, and to give its unqualified approval to the arrangement as stated by Dr. McNary. —ED.]

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE. SECTION ON GENERAL MEDICINE.

Stated Meeting, April 21, 1896.

REYNOLD W. WILCOX, M.D., Chairman.

THE TREATMENT OF PULMONARY TUBERCULOSIS.

DR. IRWIN HOWELL HANCE read a paper on this subject. He said that prominent among the many drugs recommended for the treatment of this disease stood creosote. According to his experience, the most convenient and most efficacious method of administering this drug was by filling capsules with bismuth, and putting a few drops of creosote on the bismuth. By this method the dose could be readily adjusted to the every varying requirements of the patient, and one was always sure of administering the creosote in an active form. Ready-made capsules containing creosote were not reliable. Guaiacol had proved quite useful in the treatment of phthisis in doses of from five to fifteen minims. When given endermically, it sometimes caused dangerous depression of the temperature, with profuse perspiration. The writer said that he had used it hypodermically, and had seen very fair results as regards controlling the temperature. Guaiacol would probably never take the place of creosote. It was best given hypodermically in thirty-three per cent. solution of sterilized sweet almond oil. Hydrotherapeutics had been recommended by several observers—in this country, chiefly by Baruch. The most useful form of it for phthisical patients was the rain-bath, given at an average temperature of 65° F. The tuberculin treatment is still used by a few; (1) as a test for tuberculosis in the early stages; and (2) cautiously administered in small and gradually increasing doses until the disease process has been arrested. The writer believed that it could be safely used for diagnostic purposes, and he had used it in this way with satisfaction. He believed also that the patients who had been cured by the climatic treatment, together with the use of tuberculin, had greater power of resistance against subsequent infection than those treated by the climatic method alone. As to the climatic treatment, the author said the locality should be two thousand feet or over above the sea, with a sunny exposure, with comparatively slight variations in temperature, and where the air is free from such contamination as arises from a near-by city or town.

The reader of the paper divided phthisical patients into two classes; (1) the febrile, and (2) the non-febrile. The former, he said, required to be treated out-doors until the temperature remained practically normal for a number of weeks continuously.

These patients should be given constant exercise, but they should never be allowed to exercise to the point of fatigue. This treatment should be aided by good nourishment and the internal use of creosote and cod-liver oil unless the stomach rebelled. He insisted that the too common practice of deceiving phthisical patients always bore bitter fruit; it was much better to tell them the truth and advise them promptly regarding what was best to be done. If the patient had had hemorrhages, there was danger of recurrent hemorrhages, with the consequent exhaustion.

DR. BEVERLY ROBINSON said that while he was one of the first to call attention to the creosote treatment, he wished to disclaim any idea of originality in this connection. More than this, he believed that Bouchard had done more than any other one in establishing the creosote treatment for phthisis on a firm basis. Bouchard laid great stress on one fact of great importance, *i.e.*, that the creosote must be administered in an alcolholic solution. He had therefore begun the treatment by the administration of the creosote in glycerin and whisky. He had found that pure glycerin was often absorbed and assimilated by many persons in such a way as to take the place largely of cod-liver oil, particularly in summer. He had tried various forms of pills and capsules, but was convinced that the alcoholic solution was the best method. He felt that the Germans were wrong in the attempt to give extreme doses of creosote; it certainly could not be tolerated by many stomachs here in America. For the last three or four years he had used creosote in the form of inhalations, and with the greatest confidence. An alcoholic solution of creosote is added to hot water, and by means of a croup-kettle, or similar apparatus, the room is kept filled with the vapor of the creosote. The patient was directed to spend an hour or more, two or three times a day in a room filled with this vapor. When used in this way it occasionally caused an obstinate headache, and this could only be controlled by temporarily discontinuing the creosote. It was only when the creosote was pushed to the extreme limit that he had observed any deleterious effect on the kidneys. Still, it was well to test the urine once a week. He was not prepared yet to state how creosote acted; it was probable that it acted, (1) by promoting the general nutrition, and (2) by rendering the "soil" inimical to the growth of the tubercle bacilli. The fact that the soil was an exceedingly important matter was well shown by the many patients who retained the tubercle bacilli most obstinately in their systems, and yet for long periods of time they would be quite comfortable notwithstanding the presence of these microbes. Regarding the climatic treatment, the speaker said that patients did better in the high altitudes of Switzerland than in those of Colorado, particularly as regards a less tendency to hemorrhages. For patients who, when in health, dreaded cold weather,

he did not think the Adirondacks were suitable; it was much better to send them to Asheville, N. C., or to the sandhills of Georgia, near Augusta. He felt convinced that if proper sanitaria for consumptives could be established in this country in the vicinity of sulphur springs, it would be a decided advance. This was no new thing, for it was a common practice in France to send phthisical patients to such resorts. As he believed hydrotherapy was in the main too severe for phthisical patients, and had but little faith in it, he had had comparatively little experience with it.

Dr. Andrew H. Smith said that we were justified in approaching a case of pulmonary tuberculosis with some degree of hopefulness. We should also realize that the tubercle bacilli almost never get an active hold except where the system is in an abnormal condition, From this it followed that there was an antecedent aberration from perfect health, and to this we should first of all direct our attention. Another point which he desired to emphasize was that the ideal treatment was made up of a mass of minute details, and that reliance was not to be placed on any one thing to the neglect of others. Anything which was likely to improve the general nutrition of the patient should receive the physician's earnest consideration. A minute study should be made of the individual requirements as to diet; it was quite possible to overfeed these patients, and do them harm thereby. Where the stomach was inadequate for the demands made upon it he had resorted to rectal alimentation with great satisfaction. He cited one case in particular, of very advanced phthisis, which had been marvelously improved when almost at death's door, simply by the use of enemata of defibrinated beef-blood. All the usual methods of treatment had been previously tried, together with the rest and other advantages which a good hospital could afford, yet no improvement had been noticed until the adoption of the rectal feeding. He had seen the ability to take and assimilate food very decidedly increased by the use of oxygen inhalations. In his opinion, the condition of the blood should be more carefully studied than is usually the case. The florid appearance of the face often misled the physician into the belief that the blood was in good condition, whereas, in reality, there might be present a condition of extreme anemia. Another therapeutic resource which he considered of benefit was pulmonary gymnastics. If the catarrhal condition found in these individuals in the apex of the lung were controlled, the soil would be rendered less favorable for the tubercle bacillus. He believed that the benefit derived from the creosote was largely due to its action in checking the bronchial catarrh. Measures, which had for their object the free distention of all portions of the lung were calculated to do much good in a certain class of cases. Playing on wind instruments often acted beneficially in this way. The best results in the way of the climatic treatment in this country that he had seen had been in patients who had been sent to El Paso. The climate is exceedingly dry, and there are sand-storms there, but these did not seem to exert any pernicious influence on the phthisical patients. The only drawback at present was the lack of proper hotel accommodations.

Dr. S. Baruch said he would regard it as very expedient to express any but a very guarded opinion regarding the patient's true condition until he was thoroughly acquainted, not only with the exact extent of the disease process, but also with the temperament of the individual. Minute attention to detail was important. The patient should be seen as regularly, if not so frequently, as a case of typhoid fever or pneumonia. It is just as important to keep a diurnal record of the temperature and other vital signs as in an acute disease. He was of the opinion that the successful treatment of phthisis stood upon the tripod—air, water, and diet, In view of the very varied climates usually recommended, he did not lay as great stress as many did upon the climatic treatment of pulmonary tuberculosis. Any climate which possessed a pure, dry air, and was free from dust, and moisture, and rapid variations of temperature, seemed to him to answer the purpose very well. The fact that a large number of the cases treated at the Montefiore Home, in an exposed situation on Washington Heights, gained decidedly in weight, and approved in general nutrition, was sufficient evidence that much good could be accomplished without change of climate. The "air" treatment consists in exposing the patient to fresh air day and night, as can be done in sanitaria. The cardinal rule should be that patients, with a temperature over 99.5° F., should not exercise at all, but should rest in the open air, and sunshine, while covered with warm clothing. The stimulating effect of proper hydrotherapy on the cutaneous vessels was beyond cavil. It could and should be done without shock. It was not safe to use water of a temperature below 65° F., or at a pressure below twenty-five pounds. Philadelphia cream cheese, which consists of the entire milk without the whey, was an excellent article of diet for phthisical patients. He had found that creosote usually disturbed the stomach, and was of but little value except for bronchial complications.

Dr. Henry P. Loomis said that he had never seen the beneficial results from tuberculin which had been described by Dr. Hance. There were certainly a larger proportion of hemorrhages at the Adirondack sanitarium than in many other similar places. He agreed with the reader of the paper that it was decidedly the best plan to tell the patient plainly and frankly the nature of his malady. He had become convinced that the method of employing creosote advocated in the paper was the best one, and he had used it for a number of years. The climate should be chosen in accordance chiefly with the individual temperament, rather than with reference to the disease. In his opinion the dietetic treatment came next in importance to the climatic treatment. He would divide the disease into three stages, with reference to the condition of the stomach, viz.: (1) Where no gastric disturbance exists; (2) when no solid food can be taken; and (3) from the time no solid food can be taken until the case terminates fatally. These stages, he had found, did not ordinarily correspond with the changes in the physical signs. In the first stage, three meals a day were not usually sufficient. The mat-

ter of stimulants had not yet received consideration in this discussion. He felt that in the first stage stimulants should be avoided, unless it be in the form of porter, taken with the meals. Stimulants are more useful in the last stage.

Dr. Walter James said that nothing had been said about the importance of the patient's mental attitude toward his disease. He thought we must now admit that nervous or mental influences constantly interfere with or assist us in our efforts to battle with disease. Grief or sudden depressing influence seemed to him to be a common cause of exciting the disease to renewed activity. He believed that we should tell the patient plainly the nature of his disorder, for otherwise we could hardly hope to secure the necessary cooperation of the patient. The tuberculin of some years ago was a failure, yet there were elements connected with it which seemed to indicate that there might be yet much of value in it. The fact that phthisis was treated by creosote by so many different physicians in all parts of the world showed that the treatment must be of some value. Personally, he was of the opinion that, in addition to its beneficial influence on the general nutrition, there was some, perhaps slight, specific action. He had tried the effect of creosote on other cases than phthisis, in which the nutrition was defective, but had not observed the very decided benefit so commonly seen in phthisis. In some cases he believed that very small doses of codein or morphin were indicated in addition to the creosote in the early stages of the disease. In prescribing climate, we should select one materially different from that in which the patient had acquired his disease.

Dr. Achilles Rose said that he had been informed that in the Montefiore Home and other similar institutions there had been an alarming number of tubercular infections. This was certainly a serious disadvantage in such sanitaria.

Dr. Woods Hutchinson of Buffalo said that the whole trend of the discussion had been in favor of measures having for their object the increase of the resisting power—in other words, improving the strength and activity of the leucocytes. Phthisis, he said, was undoubtedly a disease of weaklings. Any climate, therefore, which would encourage the individual patient to live outdoors should prove beneficial. The same might be said of medicines, for almost everything in the materia medica had been recommended for this disease. Among the lower animals in their natural wild state, it should be noted that there was a special immunity to this disease. The same might be said of human beings, for the Indians of the Pueblos were subject to it, while the Indian in his native wilds was comparatively exempt from it. In the lung was to be found the youngest tissue in the human body; the last organ to appear was always the first to go. Thus, in the lung itself, the apex is an atrophying rudiment, and it is just here that tuberculosis develops in about ninety per cent. of the cases. The right apex is now considered to be the atrophying rudiment of a lobe which originally extended up toward the jaw. Where growth is going on rapidly in the bones, *e.g.*, the extremities, we found a peculiar tendency to the development of tuberculosis. A similar remark applied to the intervertebral cartilages, where Pott's disease was so liable to occur. Therefore, from the standpoint of comparative pathology, the same conclusions seemed to be reached as had been arrived at by clinical research and treatment. He thought we had in our own tissues a more effective protective agent and antitoxin than the venom of the rattlesnake against the enemies about us.

Dr. Hance, in closing the discussion, said that he had been particularly interested in the discussion, because it had enlightened him regarding the effect of the medicinal treatment of pulmonary tuberculosis irrespective of the influence of climate. Any one who had heard the bitter upbraidings and reproachful remarks of patients coming to the sanitarium, because their physicians had not told them at the outset the nature of their trouble, could hardly fail to be convinced of the expediency of being frank with such individuals. Regarding the statement as to the unusual frequency of hemorrhages in the Adirondacks, he would say that in most instances it would be found that that these hemorrhages had been brought about by imprudent exercise. As a nutrient he had found it advantageous to use somatose, made into a paste with hot water, and then dissolved in milk or cocoa. Its flavor was agreeable. He had found that slight stomach derangements yielded readily to the use of a preparation known as aquozone. As a general rule, it might be said that stimulants were not advisable in the first and second stages. In conclusion, he expressed the opinion that climatic treatment was *the* method; it was certainly the one which medical men adopted most promptly when they found themselves afflicted with pulmonary tuberculosis.

REVIEWS.

Outlines of Materia Medica and Pharmacology. A Text-book for Students. By H. M. Bracken, M.D., Professor of Materia Medica, Therapeutics, and Clinical Medicine, University of Minnesota. Philadelphia: P. Blakiston, Son & Co.

It is easy to understand the purpose of this book, but why it should come from the hand of a college professor, and why it should seek circulation outside of the circle of his own students is not so plain. It is a compilation of the pharmacopeia, and of a number of well-known handbooks, such as Curtis' "General Medicinal Technology," and Wood's "Therapeutics." The book will be of practical use to students pursuing a course of college lectures, as furnishing a series of pegs upon which to hang a completer knowledge of Materia Medica. The author has not designed the book as one from which to learn practical therapeutics, nor as a book of reference for practitioners, and indeed the absence of suitable indexes would render it useless for any such purpose. As a book of reference for undergraduates, in their attempt to memorize medicinal technology the book will fill a place, such as is usually supplied in each center of medical education, by some enterprising student or quiz-master.

An American Text-book of Surgery for Practitioners and Students. By Charles H. Burnett, M.D., Phineas S. Connor, M.D., Frederick S. Dennis, M.D., William W. Keen, M.D., Charles B. Naucrede, M.D., Roswell Park, M.D., Lewis S. Pilcher, M.D., Nicholas Senn, M.D., Francis J. Shepherd, M.D., Lewis A. Stimson, M.D., William Thompson, M.D., J. Collins Warren, M.D., and J. William White, M.D. Edited by William W. Keen, M.D., and J. William White, Ph.D., LL.D. Second edition. Carefully revised. Philadelphia: W. B. Saunders, 1895.

Three years is a short period in the history of medical science, but so rapidly have improvements followed one another in surgical matters, during the past three years, since the first edition of this text-book appeared, that, in revising the work, it was found necessary to add some topics and to amplify others.

The lacunæ, which the reviewer of the first edition was able to point out, have been, in a great measure, filled, and such chapters as that of the Hartley-Krause method of removing the Gasserian ganglion; the use of the Murphy button in intestinal anastomosis; castration for the cure of enlarged prostate; Witzel's method of doing gastrostomy; that on symphyseotomy, and a number of others, have prevented the reviewer of to-day from readily discovering a subject which has been omitted. There were, too, in the first issue, certain errors which escaped the notice of the editors and proof-readers. Some of these have been corrected in the text, others by inserted slips, while others have still eluded observation, and remain for the student and reader to discover. Under "Anesthetics," cocain receives less attention than it deserves, and the man who did so much to bring its value into prominence deserves a better fate than to have his name appear as "Kohler."

The subject of erysipelas is inadequately treated, and ichthyol, which has surely proven itself a most valuable remedy, is not mentioned.

The surgical diseases of the skin are not discussed in a manner worthy of such a work, and the treatment recommended often leaves much to be desired.

Little is said about the treatment of inoperable malignant growths by injections, especially with the toxins of erysipelas, but since the gravest doubts exist as to this method ever being of real utility, perhaps the less said about it the better.

The personal element, which is so attractive a feature of the writings of a single author, when he is a master of his subject, is almost totally lacking in a work of this kind. It is further to be regretted that the name of the writer is not indicated for each individual chapter, since it naturally often adds interest to know to which particular one of the collaborators the views advanced should be attributed.

Passing to the more strictly surgical portions of the work, and especially to those chapters which deal with actual operative work, and the descriptions of technic, and we find here so much to admire that we forget almost to criticize. Every surgical disease and every operation having a just claim to recognition has been at least touched upon, while many have been discussed at length.

All that is best in American surgery is here adequately reflected, but the objective point of making this an American text-book of surgery, and not simply a text-book of American surgery, has never been lost sight of.

The art of book illustration has reached a high degree of perfection, and one unwittingly forms an opinion of a work nowadays by glancing over the pictures. Such a course would do an injustice to the text in the present instance, for, while the cuts and plates are numerous, they are by no means of superior beauty of execution.

Clinical Lectures on Abdominal Surgery and Other Subjects. By Charles T. Parkes, A.M., M.D., Late Professor of Surgery Rush Medical College, etc. Edited by Dr. A. J. Ochsner, Chicago. The W. T. Keener Company, 1896, pp. 477.

This memorial volume contains an account of more or less of the clinical and experimental work of an ardent and gifted surgeon.

The lectures on abdominal tumors, which occupy the first part of the volume, are particularly lucid and attractive in style, and clearly account for the strong hold which the writer had as a teacher. They are followed by lectures on gunshot wounds of the stomach, including experimental work indicating careful and cultivated observation, renal calculus, and surgical operations upon the kidney, tuberculosis, and general clinical surgery.

The impression which is produced by the reading of this volume is essentially the earnestness and intensity of the writer. The field which he occupied must have been a large one, and the gap caused by his too early departure must be correspondingly large. His friends who cherish his memory have good reason to rejoice in this permanent record of his useful life and services.

The International Medical Annual and Practitioner's Index. By Thirty-seven Contributors. New York: E. B. Treat, 1896. Pp. 728, (including forty-six introductory pages and full-page illustrations).

The present is the fourteenth year of this work of reference for medical practitioners, and is so far up-to-date that the new photography is not omitted. Concerning this compilation of abstracts there is but little to remark. It shows much industry and considerable reading, and will doubtless be useful to the practising physician. We could wish that more representative papers had been studied in some instances, and that the more recent literature had been drawn upon. Of noteworthy sections may be mentioned Hare's therapeutic review for the past year, and the special articles by Thies, Jennings, Thorburn, and Smith. The last, however, does not completely cover the literature.

Although the space devoted to the several departments is not always in accordance with their relative importance, yet a study of this work will be of benefit in enlarging the knowledge of the careful practitioner.

THE NATIONAL FORMULARY (Supplement to the National Dispensatory). Philadelphia and New York: Lea Brothers & Co., 1896. Pp. 115.

THIS new and revised edition contains 454 formulas. Some of these are from the "United States Pharmacopeia" of 1880, others are from various official sources, and many are formulas the result of careful experiment, to meet a demand for elegible preparations of commonly used drugs. The arrangement is alphabetical, synonyms are frequent, and considerable information besides that of mere preparation is contained in these clearly printed pages. This should be conveniently at the hand of every physician who wishes to meet indications with accurate dosage and acceptable preparations. By strictly adhering to the nomenclature and authority of this volume, the various trade preparations which are lauded in advertising pamphlets would soon fail of finding a market, and the progressive practitioner would find his usefulness increased.

THE RETROSPECT OF MEDICINE. Edited by JAMES BRAITHWAITE, M.D., Lond., Obstetric Physician and Surgeon to the Leeds General Infirmary, etc., assisted by E. F. TREVELYAN, M.D., Lond., B. Sc., M. R. C. P., Assistant Physician to the Leeds General Infirmary, etc. London: Simpkin, Marshall, Hamilton, Kent, & Co., 1896. Vol. 112. Pp. 431.

THE convenient volume which summarizes the progress of medicine and surgery for the last half of the preceding year, comes to us bearing the same evidence of careful reading, accurate abstracting, and judicious selecting, which have made Braithwaite the mentor of progressive practitioners for more than half a century. Although of small bulk, this volume fairly represents the real advance of the science of healing.

COLOR-VISION AND COLOR-BLINDNESS, A Practical Manual for Railway Surgeons. By J. ELLIS JENNINGS, M.D. Philadelphia: The F. A. Davis Co., 1896. 8vo., 110 pages, with a colored plate and twenty-one photo-engravings.

THIS little brochure, neatly gotten up, discusses concisely and clearly, the subject of color-blindness, and the methods of detecting the same. The tests employed are Holmgren's and Olliver's modifications. The author is to be congratulated in that he goes no farther into the abstruse physics of the subject than is essential to clearly elucidate the points under discussion. The book cannot but prove of great value to those for whom it is written.

MATERIA MEDICA AND THERAPEUTICS. Third edition. JOHN V. SHOEMAKER, M.D. Philadelphia and London: The F. A. Davis Co., 1895. Pp. 1100.

IN the preface to this, the third edition, the author makes particular mention of the fact that the two volumes of previous editions have been combined into one. In the two years that have elapsed since the second edition, much new material has been added with reference to hydrogen peroxid, trional, and various compounds of naphthol and phenol, and a number of sections deal with drugs discovered since the publication of the second edition. Revisions have also been made to conform with the U. S. P. of 1890. The volume, of a little over 1100 pages, is clearly printed on paper that is smooth, without reflecting a glare of light.

In any scientific treatise, dealing with a successsion of separate items, the choice must be made between systematic and alphabetical arrangement. For a lecture course and for a text-book for students, the former is a preferable, but, considering the impossibility of making a satisfactory classification of drugs, the author has done wisely in putting before the practitioner, an alphabetical arrangement of the materia medica.

We regret that the metric system has been practically ignored. Although the statements of doses in grains and of proportions in grains to the ounce, will doubtless suit the majority of the profession, we do not think that the convenience of the very considerable minority of metric prescribers should have been entirely ignored, especially as the apothecary's system is no longer official except by tolerance. Except for comparatively unimportant drugs, black-letter headings divide the discussion according to pharmacology, physiological action, and therapy. Each subject is handled concisely but quite fully.

ANNOUNCEMENT.

TETANUS ANTITOXIN.

TETANUS ANTITOXIC SERUM.
PREPARED IN THE BACTERIOLOGICAL LABORATORY OF THE CITY OF NEW YORK.

THE NEW YORK CITY HEALTH DEPARTMENT is prepared to furnish antitoxic serum for the treatment of tetanus. Each vial contains 20 c.c. of serum, having an immunizing power of 1 to 3,000,000; *i.e.*, one c.c. of serum protects three million grams of guinea-pigs in weight from a fatal dose of tetanus toxin. The average initial dose of the serum varies with the age of the patient, the gravity of the case, and the time when treatment is begun.

The remedy is administered by deep hypodermic injections, a large syringe (such as has been employed for diphtheria antitoxin) being preferably employed for the purpose, although an ordinary hypodermic syringe carefully cleaned may be used, the barrel of the syringe being repeatedly filled. Some point on the anterior surface of the body should be chosen for the injection, where there is an abundance of subcutaneous cellular tissue, as the anterior surface of the abdomen, or thorax, or the outer surface of the thigh. Before the remedy is administered the skin should be carefully washed with alcohol, or some disinfecting solution, and the syringe carefully sterilized and then washed with sterilized water. The solution is rapidly absorbed, and it is better not to employ massage over the point of injection.

IT IS OF VITAL IMPORTANCE IN TETANUS THAT THE ANTITOXIN BE ADMINISTERED AT THE EARLIEST POSSIBLE MOMENT, AS THE DOSE REQUIRED TO NEUTRALIZE THE TETANUS TOXIN ABSORBED INCREASES WITH GREAT RAPIDITY WITH EACH HOUR'S DELAY.

When the treatment is begun at the first appearance of

tetanic symptoms and they do not point to a very severe infection, and especially when the incubation period has been long, *e.g.* two weeks; one vial, or 20 c.c., may suffice for the first injection, and, according to the results, one-half the quantity or the same quantity should be repeated at intervals of from six to twelve hours during the four following days.

If the infection is intense, as shown by a short incubation period, *e.g.* five to eight days; or by the rapid development of the tetanic symptoms, and by the predominance and intensity of bulbar phenomena, or if the treatment is begun several days after the appearance of the tetanic symptoms, even if at the time of injection they are not severe, the contents of one vial should be at once injected, and the dose repeated at short intervals, according to the effect produced on the tetanic symptoms.

The doses required where the wound has been previously untreated, even if the symptoms are slight, are usually large. The dose for children under twelve should be one-half or less that for an adult. The use of tetanus antitoxin does not preclude the employment of other remedies, such as chloral, the bromids, physostigmin, or morphin. Some one or more of these remedies should be employed in full doses. It is also thought to be advantageous to give large amounts of water to the patient for its diuretic effect, as the tetanus toxin is eliminated by the kidneys.

Where tetanus follows some wound of the surface, this should be treated freely with some preparation of iodin in solution, to destroy the toxins in it. The ordinary antiseptic solutions, such as carbolic acid, and bichlorid of mercury, are of little value for this purpose.

The exact value of tetanus antitoxin in the treatment of this disease, and the best method of administration, have not been fully determined, and the Health Department of the City of New York specially requests that all persons using this preparation of antitoxic serum will forward a full report to the Department of the case, and the results of treatment.

All public institutions in New York City, on application, will be furnished with tetanus antitoxin free of charge.

Address "The Bacteriological Laboratories," Health Department, Criminal Court Building, Centre street.

Telephone, "448 Franklin."

Approved by the Board of Health at a meeting held May 19, 1896.

Charles G. Wilson,
President.

Emmons Clark, *Secretary.*

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from May 5, 1896, to May 11, 1896.

Major Daniel G. Caldwell, Surgeon, having been found incapacitated for active service by reason of disability incident to the service, is, by direction of the President, retired from active service this date, May 2, 1896.

Captain Charles E. Woodruff, Assistant Surgeon, now at Fort Sheridan, Illinois, is detailed for temporary duty as Attending Surgeon in Chicago, retaining his station at Fort Sheridan.

From May 19, 1896, to May 26, 1866.

Captain Richard W. Johnson, Assistant Surgeon, granted leave of absence for thirty days, to take effect about May 14, 1896.

Lieutenant Colonel William E. Waters, Deputy Surgeon General, granted leave of absence for two months, to take effect on or about July 1, 1896.

Major H. O. Peuley, Surgeon, granted three months leave of absence, to take effect about July 1, 1896.

First Lieutenant James M. Kennedy, Assistant Surgeon, Fort Missoula, Montana, ordered to Fort Yellowstone, Wyoming, for temporary duty with troops in the field, in the National Park, during the season.

Promotions.

To be Assistant Surgeons, with the rank of Captain, May 4, 1896, after five years' service:

First Lieutenant William F. Lippitt, Jr., Assistant Surgeon.
First Lieutenant Merritte W. Ireland, Assistant Surgeon.
First Lieutenant George M. Wells, Assistant Surgeon.

Official List of the Changes of Station and Duties of Medical Officers of the U. S. Marine Hospital Service for the Fifteen Days Ended May 15, 1896.

Murray, R. D., Surgeon. To inspect quarantine ports on Gulf Coast of Florida, West of and including Apalachicola and the coasts of Alabama and Mississippi, May 1, 1886.

Bailhache, P. H., Surgeon. To inspect quarantine ports on the coasts of Connecticut, New York, and New Jersey as far South as Sandy Hook, May 1, 1896.

Purviance, George, Surgeon. To inspect quarantine ports on coast of New Jersey, South of Sandy Hook, and on Delaware Bay and River, May 1, 1896.

Sawtelle, H. W., Surgeon. To inspect quarantine ports on the coasts of Louisiana and Texas, May 1, 1896.

Austin, H. W., Surgeon. To inspect quarantine ports from Northern port of Maine, to extreme northern port of Rhode Island, May 1 1896.

Stoner, George W., Surgeon. To inspect local quarantine station at Baltimore, Md., May 1, 1896.

Godfrey, John, Surgeon. To inspect quarantine ports on the coast of California, May 1, 1896.

Carter, H. R., Surgeon. To inspect Cape Charles Quarantine Station, and quarantine stations at Newport News, Norfolk, and Richmond, Va., and quarantine ports on the coasts of North and South Carolina, Georgia, Florida, and the coast east of Apalachicola, excluding Key West, May 1, 1896.

Peckham, C. T., Passed Assistant Surgeon. To inspect quarantineports on the coast of Washington, exclusive of ports on the Columbia River, May 1, 1896. Granted leave of absence for thirty days on account of sickness, May 15, 1896.

Hasdin, Eugene Passed Assistant Surgeon. Granted leave of absence for two days from May 14, 1896.

Guiteras, G. M., Passed Assistant Surgeon. To inspect local quarantine station at Key West, Fla., May 1, 1896.

Perry, J. C., Passed Assistant Surgeon. To inspect quarantine ports on the coast of Oregon and the Columbia River, May 1, 1896.

Sprague, E. K., Assistant Surgeon. To proceed from Mobile, Ala., to Boston, Mass., for duty, May 1, 1896. To defer departure for Boston, Mass., until return of Surgeon Murray, May 6, 1896.

Cumming, H. S., Assistant Surgeon. To proceed to Norfolk, Va., for temporary duty, May 12, 1896.

Mathewson, H. S., Assistant Surgeon. When relieved at Boston, Mass., to proceed to San Francisco, Cal., for duty, May 1, 1896.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXVIII. NEW YORK, SATURDAY, JUNE 6, 1896. NO. 23.

ORIGINAL ARTICLES.

ADDRESS OF WELCOME TO THE AMERICAN GYNECOLOGICAL SOCIETY.

BY WILLIAM T. LUSK, M.D.,
OF NEW YORK.

A SHORT time ago our honored president called upon me to say that he desired that I should this year deliver the address of welcome, and to my demurrer recalled to me the fact that the choice had fallen upon me because I was now among the veterans. And yet it seems to me only a little time since I was secretly hoping that our friend Chadwick, in making up the list of those to be honored with membership, would not regard too rigidly my somewhat budding claims.

At the first meeting twenty-eight voices answered to the roll-call, and thirty-nine were chosen members. Among them were Sims, Emmet, Peaslee, Thomas, Parvin, Battey, and Goodell, all pleasant sounding names. Those were halcyon days. Barker, with his born gifts of oratory, was our first president. It is a delight, at this day, to recall his face, "Filled with a fine old-fashioned grace, fresh-colored, frank, with ne'er a trace of trouble shaded."

But twenty years have passed by. Of the thirty-nine original members only fourteen remain. A few have resigned. Most have gone to the silent land. This Society was not, however, founded that we might walk according to the traditions of the elders. It has been constantly strengthened by the accession of eager, active, progressive, younger men, who have helped greatly to keep its interests in the things of to-day.

At the first gathering, Thomas, in his address of welcome, said: "American gynecologists look with high hopes to the future of this Society." In the changes twenty years have wrought those hopes have been nobly realized. Membership is a coveted honor. Its Transactions are of the highest rank, filled not only with instructive clinical material, with contributions to pathology, and with expert criticisms of current questions, but which contain a number of papers like that of Noegerath on latent gonorrhea, of Emmet upon a new method of repairing the perineum, of Byrne upon the use of the galvano-cautery in operations for cancer of the uterus, of Polk regarding operations upon the uterine appendages with a view of preserving the functions of ovulation and menstruation, and of Henrotin upon the conservative treatment of para- and peri-uterine septic diseases, which have had a wide-reaching influence upon the practice of gynecology. Chadwick may well be proud of his creation.

The past twenty years have witnessed the perfecting of surgical methods. Wonderful as the results have been, it is to be borne in mind, however, that up to the present, surgery has been largely employed to destroy, whereas its highest function is to save organs, to preserve functions, to make the sick whole. Strictly speaking, the removal of organs should not be the ground of boasting, but should require explanation and apology. Let us indeed hope, that in the great coming work of gynecology, viz.: in the multiplication of resources for the restoration of diseased tissues to health, we will have the good fortune to take the lead.

But I will not detain you from the important business of the day. In extending to our guests the welcome of the New York members of this Society, I am reminded how Homer says that "Ajax, having won renown in war, received by way of distinction whole 'chines of beef,' it being considered that an honor which, besides the glory of it, would augment his physical strength, was peculiarly appropriate to a brave man in the prime of his manhood."

We too, on this occasion, will seek to honor our meritorious members, as we are taught was the custom in Plato's Republic, "with goblets filled to the brim, and meats, and places of honor."

A RETROSPECT OF TWENTY-ONE YEARS OF GYNECOLOGY AND OBSTETRICS.[1]

By WM. M. POLK, M.D., LL.D.,
of New York.

The honor conferred upon me, one year ago, makes it my province and privilege to address you from your president's chair upon this, your twenty-first anniversary. The three sevens composing the period, comprising infancy, childhood, and youth, culminate in the twenty and one, which marks the boundary between youth and manhood. But he would be a bold man who, in any day, month, or year of your existence, had denied you the attributes which pertain to maturity, or had questioned the possession of the graces and accomplishments which mark the attainment of years of discretion.

Like Minerva Medica, you sprang full armed and capped from the busy brain of that wise and active ambition which has ever since shaped your successful and beneficent course.

Launched into the arena, this Society at once exercised those guiding functions which age and experience warrant, and which have ever been justified by its subsequent course. Is it any wonder, then, that I should feel abashed, rather than elated, when here in your presence, in this city of your birth, in a chair hallowed by the lofty spirits of predecessors who touched the springs of action in a way none of us can rival, I attempt to address you as your presiding officer? I do indeed thus stand before you to-day, and seeking for a theme wherewith to gain your ear and lead your thought, have not been able to do better than seek my inspiration from those who have preceded me.

Looking over the addresses which have marked your annual gatherings, I have found in that of your first president the line of thought I shall endeavor to present to you to-day.

The erudite and genial Barker found ample store in casting a retrospective eye over the field of science and practice, which stretched back over the hundred years preceding your advent. With here and there a towering peak, such as the initiation of ovariotomy and anesthesia, the view, as a whole, suggested perhaps too much the calm, unbroken aspect of the plain. But, peaceful as seemed that repose, one could hear the distant rumbling and feel the swaying undulations, which told the coming of upheavals soon to break and throw in rugged, unformed masses the ground on which you stood. To you, as much as to any one body of men, fell the task of meeting and shaping the outcome of this upheaval. Forewarned, you came forearmed, and he who reads your deeds, as chronicled in the volumes of your "Transactions," can but be proud to find himself one of such a band of fearless, able workers for truth. In retrospect, I too shall hope to find my inspiration, restricting it to the twenty-one years covered by your existence.

My task is all the easier, seeing that of all the potent, far-reaching questions raised by the upheaval, not one has escaped searching inquiry at your hands, and many have found their solution in your work.

Even before your birth, the impress of Pasteur's work was such that already there were signs of revolt against the accepted theory of inflammation. No one could be more keenly alive to the possibilities of the situation than the men who worked here, for of all who dealt with the mysteries of injuries and repair, they trod upon ground most exposed. The organ constantly before them for investigation and treatment had a more direct connection with what was then classed as a "vital spot" than any other in the body. And this so-called vital region, the peritoneal area, was more so because of its ill reaction to inflammation than from any other cause, and the frequency with which it became inflamed after interference with the uterus, marked the latter organ with dangers which terrorized all who approached. For who could fail to hesitate before and perhaps dodge the issues presented by an organ which, if but scraped by a curette or incised at its outer face, would respond by initiating a fatal peritonitis. And if dread-oppressed when dealing with the peritoneum at this long distance, how much more must it have weighed upon him who contemplated a direct attack upon it. Scant comfort could be found in contemplating the best results obtainable, even by the expert in abdominal surgery. A mortality of twenty-five per cent. did not conduce to confidence, especially when he found that the seventy-five per cent. successful issues had come in many only after dire experience with surgical, now better known as septic fever. With a braveness of spirit which we, in our smooth course along the same road, can hardly appreciate, he fought on, dismayed at times, no doubt, but not disheartened. Questioning himself he asked, where lay the defect? Could it be in manipulative skill, he set himself to improvement here. Perhaps it resided in the patient, so every detail of bodily action was scanned, with a view to improvement. Perhaps it lay in atmospheric changes, so certain

[1] The President's Address, delivered at the twenty-first meeting of the American Gynecological Society, in New York, May 27, 1896.

seasons of the year were condemned as unfit for such delicate work. Hospitals were brought under suspicion, unless they possessed special and elaborate systems of ventilation. And so suspicion turned from one thing to another, and still the evil eluded detection. The surgical mind had finally come to view inflammation in injury of any kind as an element of doubtful good, or, at best, as something forced from nature as a protective agent against an evil which should not exist, at least in traumatism inflicted by the surgeon. In the abscence of proof that it was any one particular thing, opinion finally rested upon the conclusion that dirt or filth of some sort was the offending matter. And leaping in a bound across the whole field yet to be illuminated by bacteriological research, with unerring instinct it placed its finger upon the fault. But when action was deduced therefrom, the lack of knowledge of the essence or nature of this fault led to measures of eradication, which in themselves led up to results too much related to those it had been hoped to eradicate. Thus it was that wounds, even in your day, were treated not wholly unlike they were in the days of Paré; and we would not marvel if the sprays in which you worked had at times clouded the renal epithelium of more than one of you. But, spite of it all, you lived to see the day when the essence and nature of the fault lay bare. The patient labor of bacteriology has shown it to you, and in so doing has permitted you, above all men, not merely to share, but to lead in the triumphal march of modern surgery.

But a short time before this Society was organized, the field of gynecology was largely dominated by the cervix; in fact, it is scarcely an exaggeration to affirm that the cervix so far obscured the remaining pelvic field that many would-be gynecologists contented themselves with treatment of what could there be found. In view of this state of things, and in face of the methods of pelvic investigation even then pursued by the profession at large, it is not surprising that the leaders who pointed to other fields should have been met by the oft-repeated assertion of his compeers in other fields of surgery that the sign of the gynecologist was a cylindrical speculum and a stick of nitrate of silver and that he must recognize these as his limitations.

The sarcasm seems to have cast a paralyzing influence upon the perceptions of those who justified it, for, acting well within the sphere assigned, they were content to take it as passed on to them, find in it ample excuse for endless woes and almost endless treatment. It remained for a leader in this Association to unfold the secrets of its lesions, to establish their courses, to indicate their true relation to coexistent disorders, how best to cure, and in this elucidation not only to lift what opprobrium had attached to the exclusive concern of so many with the cervix, but to demonstrate that germ of truth so often hidden in the biting word, and whose fulness so often pulls its fangs. For lesions of the cervix are far-reaching, as the labor of this man has forever proven, and yet he marked their limitations, and in doing so has met with fellow-workmen tracing boundaries in other portions of this prolific field, and he and they have so enlarged, have so elevated its plane that the scoffer, lost in admiration, turns himself to imitation, that sincerest form of flattery. It is difficult to overestimate the value of Emmet's work, but in this field we can at least approximate it. Differentiation and classification are accomplished facts, and a rational and successful treatment has been inaugurated. But the influence of his work did not cease even here; it went further, and, bringing home to us the major causes, it has done that best of all, viz.: provided prophylaxis. In these days of accepted plastic surgery of the cervix, we scarcely realize the wearying routine of treatment to which these cases were subjected, the endless repetition of that "local treatment," which, after all, left perhaps a scarred, contracted structure, cured to the uninitiated eye, yet suffering in its depths a change in connective tissue and glandular elements, themselves the pivot of continuing symptoms, which, in despair, the baffled attendant set down to conditions far outside the field whereon he had labored, as he thought, so well. And now how changed is all this. Commencing with the parturient act, we mark the beneficent influence of this man's work throughout the life of every mother. Note the consideration now bestowed upon the cervical segment of the uterus in labor, the care, if torn, with which it is guarded from the influence of sepsis, a care mainly dictated no doubt by the need for immediate protection from the dangers of a general sepsis, but also by what we now know to be the local, as distinct from the constitutional action of such a process upon the lacerated surfaces. What woman is now declared well after parturition before the effects of labor upon the cervix have been studied, and, if need require, remedied; and if she comes to us a sufferer because of lack of this care and treatment, is not our task made easy by what this man has taught us? But great as is this boon, there is another which calls for grate-

ful recognition from every woman compelled to endure the pangs of powerless labor. It is his insistance upon the early use of forceps, not merely to end the strain of unsuccessful effort, but to protect her tissues from that necrotic process, which, coming from the long-sustained pressure of the fetal head, leads direct to fistula of bladder or rectum. Lesions long set down to the use of the obstetric forceps are now known to result more often from delay in use. It was a high privilege to demonstrate and preach such truths; it is more than a privilege to follow such a leader.

Happy is the man who, realizing the baneful influence of conditions revealed at autopsy, yet hidden during life from view, who, baffled in his efforts to unravel them, finds himself at last upon the vantage-ground from whence the evil can be watched in its course, from whence it may be checked. We all can feel this joy, for of all the diseases coming under our care, none have been so elusive as those of the bladder and its associate organs. About the time of your birth, headway had been made in this research, but it is only within the last few years, unqualified success has crowned it. Now direct inspection and treatment of the bladder can be had without violence to its integrity or that of its outlet. This certainly is a great advance for our work. For long we watched the evolution of this method, anxious and willing to seize upon and apply it, for who of us has not had his defeats in time past in this field? Who has escaped the impotent conclusions of at least one case of vesical disease?

Spurred on by dire necessity, we irrigated and distended, we buttonholed urethra as well as bladder, thrust in this and that speculum, and blindly cauterized, but all to little purpose in far too many instances, or, perhaps at the cost of such discomfort to the sufferer as made her shrink from an infliction scarcely less annoying than the state for whose cure it was instituted. And yet, these measures paved the way for that direct and harmless inspection by light conveyed or reflected into the bladder, along a natural channel, which we now enjoy. But it stops not here. What was the relation of your predecessors to disease of the ureters and the pelvis of the kidney? The need to bring those regions more nearly before us was as urgent then as now, and we had already been taught how we might search them with bougies. It were a waste of time to dwell upon this good work, to follow it through the recorded labors of Simon, Emmet, and Bozeman, for it is as familiar to this audience as the alphabet, and yet valuable as it was, because of the difficulties and the lesions entailed, few pursued the method, save in extreme cases. But Kelly and Pawlick have given us the additional light, which not only places the secrets revealed by their predecessors in easy reach of all, but unfolds others heretofore unknown. Thus, the urinary, as well as the genital, system of our subjects, is brought before us in a manner which bids fair to gain fresh triumphs for our guild.

Allied to this subject is another whose bearing upon our problems is scarcely less than those just passed in review.

The floating and displaced kidney has long been known, and some of its evils were recognized, but still its relation to many of the symptoms presented by those who came within our sphere of action was hidden. The relation existing between kidneys of this kind on the one hand, menstruation and the digestive processes on the other, was scarcely appreciated, hence, it frequently occurred that having a patient in whom backache and digestive disturbances, such chiefly as nausea, were aggravated at menstruation, we argued from the association to some disorder of the uterus or ovaries. As few women can be found who possess perfect structures, as the uterus was known to have an influence upon the stomach and as the mysteries of the ovarian influence were as now, still unfolded, the association in question could but tend to direct us to these organs in search of the source of the disturbance. It not infrequently happened that these patients, owing to a general descent of all the abdominal viscera, were treated successfully by an abdominal supporter, and the ease obtained set down to relief of the pelvic organs from the pressure of the superimposed viscera. Moving in this circle, attention was centered upon the pelvis. Ovaries even were sacrificed, only to learn that instead of relief, symptoms were added, the whole presenting a picture worse than the first. No doubt, those ill results helped on the restless spirit of investigation so rife in our time. Be this as it may, the secret now stands exposed before us, so that fixing the kidneys and supporting the other viscera where needed, we gain relief that can be had in no other way.

Closer yet to our field is another whose pathological processes so frequently encroach upon it, we have in times past confounded the two. The vagaries of appendicitis are just beginning to be known, so that one need not always view with suspicion the right adnexa when disturbance arises in and about their region. He may, at least, consider the question open until search has

cleared or condemned them. The appendix, quite independently of the uterus and adnexa, is implicated with sufficient frequency to justify some suspicion toward it. Pain and tenderness in the right iliac region can no longer be dismissed as amenable to a waiting policy. It must be most carefully inquired after, and nowhere is our advance in differential diagnosis more evident than here, nowhere has it been productive of more good, and nowhere in our entire field do we see more clearly the light which leads through prompt action to safety,

Less aggressive than the question of appendicular disease, but more constant and, therefore, more pressing, was that of retrodisplacements of the uterus, and just now it is prolific in discussion. The successes scored in contiguous fields spurred on more than one mind to search for better things in this. Mechanical modes of relief, as distinct from the purely surgical, had held the confidence of most of us, so that as much as anywhere else mere surgery was viewed with suspicion. But so active has been the effort in surgery's behalf, more than one method has been advanced; and in this very fact lies much of the skepticism which still remains. When several plans by which to acquire a given end are presented, one feels, perhaps too often, that all are defective, and this is fostered by the criticism which each advocate bestows upon rival plans in his eagerness to extol his own above all others, for we may be sure he spares no pains to expose the weakness of others in presenting the strength of that he advocates. This is merely human. But, as said, out of it all has grown a spirit of doubt touching all the surgical methods of relief for retrodisplacements. Here, as elsewhere, we must lend our minds to the unraveling of the problem. I well remember a criticism offered upon Alexander's operation when first presented in this country, and a wise one it was. Hunter said it is not so much: can we accomplish such and such a result by a given method, but when done, is the result better than that to be obtained by the plan it is proposed to supplant? Before we can determine, then, this question's relation to the treatment of retrodisplacements, we must first settle upon the above basis which of the several surgical plans of treatment proposed surpasses all other surgical plans in its results, and then we can quickly decide as between the mechanical and the surgical. I do not apprehend you will find much difficulty in solving this, for already your minds, prone to the latter, are ready to abandon the former. To the future, then, the solving of the question must be left, and to this same future belongs the solution of another question.

If you should turn to Volume I. of your Transactions, you will find under the caption, "Extirpation of the Functionally Active Ovaries for the Remedy of Otherwise Incurable Disease," a paper by Robert Battey, which, dealing primarily with that all-important subject, touches, in passing upon this question of the future, "Vaginal *versus* Abdominal Section." Battey confined it to the needs of the situation as presented by the classes of adnexal disease to which the paper is devoted. For us it has been widened, till it now applies to the whole question of intraperitoneal pelvic surgery. I am much tempted to enlarge upon the subject, for I know it is one of peculiar interest to everyone here—to the new members, but particularly to those older members who, when most of those who now come up to our yearly gatherings were but fledglings, had pondered over, discussed, and, in some measure, elucidated its bearings. A new question then to come, it is the revival of an old one to others. And let me say, just here, that he who seeks for guidance in the mazes of this question will save himself much time in research, and gain no little in the essentials of technic, if he will only turn to the past utterances of members of this organization. For, as said, this is not a new question by any means, and, like all others which have been before the medical profession during the days of our existence, it has secured from this Association its due of consideration. A useful inquiry may be instituted as to the causes which led to the abandonment for a time of the vaginal approach to the intraperitoneal pelvic area. It lay in the greater mortality of the vaginal route. The conditions facing our predecessors were mainly those of grosser or larger dimensions, which had, perforce, to be dealt with by abdominal section. This led to the more rapid technical perfection of the latter, and the enthusiasm of successful laparotomy soon eclipsed the claims of vaginal section. Evils whose dimension and location would naturally suggest the latter approach were dealt with too easily from above to warrant effort from below. But finally an acquaintance with pelvic disease, which was only possible from above, has paved the way to a success from below which bids fair to reassert the position of vaginal section for, at least, certain of the lesser evils of the area in question, and perhaps some of its most pressing ones. Prudence warns me to desist from this prolific subject, for one can read in your look of

patient resignation your polite endeavor to accord the Chair attention at the cost of your wearied interest. This he leaves untouched, confident that in the paper of the distinguished guest who follows him this interest will be roused as can be done by none other here. To him and to the future we then leave the question, confident that when the solution comes it will have been gained only after such careful scrutiny, such candid criticism, that doubt will no longer obscure our vision, for then even he who runs may read to full conviction.

Fifty years have passed since Holmes formulated the doctrine of the contagiousness of puerperal fever, and when attacked, spite of his disclaimer that he did not intend to enter upon a quarrel over the counterpane which covers the mother with her newborn babe, he wielded such a trenchant pen he more than held his own. But, after all, it was no quarrel, but the contention of great spirits over a great theme—less contention for contention's sake than the outburst of that high and fearless independence which should always mark the advent of any revolutionary doctrine. It is needless to say that when you first met the doctrine had been accepted, and was part and parcel of your creed and practice, but in spite of the good thereby accomplished, the dread disease still held sway, as witness the papers of your earlier gatherings. You know now why this was so, for everyone here is to-day as familiar, not only with the fact of contagion, but with its essence, its sources of origin, and its methods of propagation, as he is with the simplest act of his daily practice, and yet, till this knowledge came, fear possessed the minds of all related to obstetric practice. Let your mind go back to a lying-in ward in days just preceding the inauguration of this Society. A score or more of healthy women, peacefully waiting an advent, the culmination of Nature's law and the fruition of instincts about which revolve the highest, and too often the basest, of human desire, all equally entitled to life however, if not for their own sakes, at least for that of the helpless beings for whose existence they are in part responsible, and for whose nurture they are essential.

Now look upon them in the neighboring ward, where they are entitled to rest after the ordeal of labor. Instead of the restful and quiet convalescence they now obtain, puerperal fever was then their portion far too often. Fortunate were those who at once entered upon the steep and smooth declivity of sapremia, for they at least enjoyed the repose of easy and speedy death, while others took their way to the same goal, racked with the sufferings of peritonitis and pyemia, or, if escaping, escaping only to find themselves as invalids, facing the cares of mother, wife, and household guide. Is it any wonder that we shrank from the duties of the parturient chamber, where so much doubt and danger pressed upon us? There are some of you who, on mercy's errand, have wound your way amid the dead and dying of the battlefield, where human beings lay so thick that, fearing to profane the dead or injure the living, it was needful to pause and place with care each succeeding step, and again, bent upon a like errand, you have passed from bed to bed, ministering to the wants of women, all stricken with this frightful disease. In one, the awful grandeur of death stood out before you; in the other, its misery. In one, death for high purpose, because of man's ambition; in the other, death in the highest purpose, because of man's impotency. It is easy to tell which scene impressed you most. And yet, the same spirit of ambition, acting in the less conspicuous field, has penetrated the secret of puerperal infection, and at least made safe the path which leads through parturition to motherhood. In all of this you have borne a part which should be cause for self-congratulation to every member of the Society. It has been said that he who lives in the last half of this century has seen more discovered and developed which pertains to man's welfare, his glory, and his divine attributes, than has been realized in any other period of equal length in the world's existence. I believe this to be so, and if asked to place my finger upon the one thing of all this which touches most nearly man's welfare, his glory, and his divine attributes, I must place it upon the discovery which has freed the most sacred act of Nature from the terrors of childbed fever.

In contemplating the triumph incident to parturition, one's thoughts rest for a while upon what was gained to it through invasion of the cavity of the uterus; and, had we not been chiefly mindful of that greatest gain, prevention, we might have paid, in passing, some tribute to the spirit of enterprise which formulated and placed upon a firm basis intrauterine treatment of the septic puerperal uterus. But you are familiar with it all—its advance and recession—till most of its good and its evil are so clearly before you as to leave no one in doubt as to when he should employ it and when avoid it.

Singularly enough, while contention upon this measure was waging, the seeming paradox was

presented of urgency for it in the infected parturient uterus, and urgency against it in the infected non-parturient organ. But, as wider knowledge has annulled the objection to this course in the one case, so it bids fair to set at rest all objection to it in the other, and finally open the structure by unanimous accord to treatment more in keeping with that which prevails in more exposed and less vitally connected organs, and thus reverse the assertion but lately so commonly before you, that prognosis is unfavorable in chronic endometritis and metritis.

Glancing again through the papers of your first volume, I fell upon the following sentence: "We have been taught by experience that it is not safe to perform an operation on the womb while symptoms of perimetritis exist." In other words, that when salpingitis was present, even to a degree devoid of pressing symptoms, such a thing as curettage of that uterus was forbidden. One can scarcely realize the potency of this mandate, unless he follows the evolution of pelvic surgery during the past twenty-five years. Baffled and defeated in many a case of perimetritis, we throw up our hands in helpless impotency. The douche, the pack, and time served their good purpose in some, but too many were left who, labeled "incurable," sank to hopeless invalidism, softened in those of feeble will by the soothing influence of the opium habit. What wonder, then, that we should turn a willing ear to the marvelous stories that came from Birmingham. Here, at last, was the cure for all these dreadful cases of perimetritis. But when proven, the impetus was too great to halt at them. The ease with which relief could be gained, not only for such cases, but for nearly all afflicted with chronic inflammation in and about the uterus, proved so seductive to surgeon and patient alike, the measure had too wide an application. The spirited controversies revolving about this question are things of the past, but not so the results. Out of them has come that calm to which earnest conviction sooner or later tends, and, searching ever for truth, the goal of all our work, we see that perhaps between the extremes some middle ground can be found. From this thought has come the extension of intrauterine treatment to many cases of perimetritis, which now fast becoming the accepted road to alleviation, and perhaps cure, for cases heretofore doomed, on the one hand to hopeless invalidism, or, on the other, to needless mutilation. And while this truth has been dawning, another has been slowly but surely evolved from the incomparable labors of those who attacked the perimetric lesions from within the pelvic and abdominal precincts. It is the fact that surgery here, as elsewhere in securing health, can restore to form and function organs which but lately were exposed only for sacrifice.

Thus working from the extremes of this therapeutic problem, at last we see ourselves approaching a solution which will enable us to so differentiate our cases of perimetritis we can apply that treatment which will give to each its best measure of relief.

Had I the time, and you the patience, other questions in whose solution you have taken part might be passed before you; but enough has been presented to refresh your memory and justify your claim to leadership in the great advances made in our department of surgery during the last twenty-one years. And yet, my task is scarcely finished till I pay some tribute to the members of this Society now with us who, as founders, participated in its birth, who since have done so much for its glory, and who have stood sponsor to so much of the work presented by its junior members. It has been said that the country which lives ever in the present is in danger of creating in the body politic that form of degeneration which sinks it to a level whence its glory can be seen only in its past. Time has its revenges here on earth, and sees many of them evolved where man is touched, from his disregard of laws of conduct. A common lapse just now is that spirit which must always be up-to-date—that one which must ever live in the present. You know what this product is, its superficiality, its selfish disregard of the rights of others, its brazen self-assertion, and out of this, its disregard of truth, and all because it feels some demoniac force impelling it to self-aggrandizement at almost any cost. Get on! get on! it matters little how; but Get on! Gain success, and it will be a shield quite broad enough to cover all misdeeds. This is the up-to-date spirit, the one which has no time to look back and build its conduct upon the lines already marked out; in fact, in many instances does not wish to look back, for, posing as a would-be leader, it is necessary that it should appear as an original. If the field is not new, it must at least be made to appear so. He little realizes that this same spirit is an early manifestation of the degenerative process, which, continuing, will sooner or later present him to himself as full of grace and wisdom, and to others as sounding brass. But out of a loyal devotion to one's ancestry, a jealous care of its fair name, a just appreciation of its merit, a wise appropriation of its

labors, comes a strength of character upon which the best of superstructures may be erected, from which new glories may emanate. So let it be with us. Ever loyal to our forefathers, we will look to them before we go elsewhere for inspiration and for guidance; and to those of them now left to us pay honor in ever minding them of our obligation to their wisdom, their courage, and their fidelity to the trust which they have passed to us.

Yes, gentlemen of the American Gynecological Society, they are most noble models, and in honoring them we give ourselves the highest of all honor.

THE CLINICAL IMPORTANCE OF THE MENSTRUAL WAVE.[1]

By ARTHUR W. JOHNSTONE, M.D.,
of Cincinnati, O.

When this title was given to the secretary, it was my intention to present a strictly scientific paper showing you how the lower animals menstruate. But a recent visit to New York convinced me, as much as I dislike rewriting subjects that I have already handled, that the best use I can put your time to is to ask you to listen again to the clinical importance of the menstrual wave. Menstruation, which occurs in all erect animals, is nothing but a shedding of the superficial layers of the edometrium and is a kindred process to the molt in birds, the dropping of the horns and hair in the deer tribe, as well as the loss of the dermal structures, which occurs periodically in so many different classes of animals. The lower animals menstruate through the lymphatics and the whole time between the rutting periods of the unimpregnated animal is given up to the various functions that are accomplished by menstruation in the upright animals. As the lymphatic stream cannot work anything like so rapidly as a stream of blood which finds a ready exit, of course it takes a longer time to accomplish the removal of the endometrium through the lymphatics, and therefore requires a much longer time for the thorough regeneration of the endometrium. These few statements indicate about what that paper would have been.

I have found, in talking to a number of our leading men, that the clinical importance of the menstrual wave is not appreciated as it should be. And my experience with the blunders of other people (which would have been saved had they understood this law), have convinced me that the best thing I can do is to give you a strictly clinical paper.

[1] Read before the American Gynecological Society, May 26, 1896.

As to what this menstrual wave is, who elucidated it and when it was worked out, I must refer you to a paper of mine on "The Pathological Aspect of the Stephenson Wave."[1] The man to whom this paper refers is Professor William Stephenson,[2] of Aberdeen University. I found in this paper a finished tool ready for practical use. At this time everyone in England was speaking of the Stephenson wave, and as my first paper upon the subject of menstruation was to be delivered to an English audience, I used the term they were accustomed to. Since then, both in season and out of season, I have been impressing the clinical importance of this subject, not only on the gynecologists but on the general practitioner, for I cannot see how any man can do justice to his patients, who has many menstruating females to care for who does not fully understand this whole subject. A prolific writer of this city has recently shown her ignorance of the subject in undervaluing its clinical importance, and as at one time she did some good work on the subject, I fear her influence may put the subject in a false light. She speaks of my high estimate of it as being an "evident and even grotesque exaggeration"; and in another place says it should "guide the therapeutics of all non-infectious utero-ovarian disease."

The applications that I have made of it invade every specialty embraced by our profession, and what I now propose to do is to show you how it is the great *compass*, that every man, who is dealing with menstruating women, ought to have constantly by his side, for without it, many a time he will be led to do very dangerous things and at other times will be very uselessly alarmed over comparatively small matters.

First as to menstrution itself, upon what does this law throw light? Without the definite charts of Professor Stephenson, vicarious menstruation would be an absolute enigma. Now that we know, in the most of these cases, there is a certain amount of hardening of the endometrium, which obstructs the natural outflow of the menstrual fluid, the reflex wave is thrown off to whatever point is weakest and wherever there is a pathological lesion. We now see how this blood may be poured out at different points.

Intermenstrual pain, which used to be a regular conundrum, we now thoroughly and easily understand. It comes in the trough of the wave, when the pressure is at its lowest, when the pelvis

[1] Read before The Cincinnati Obstetrical Society in 1895, and published in volume xxxi of the *American Journal of Obstetrics*.

[2] See his original article in the *American Journal of Obstetrics* for April, 1882.

is anemic and every organ is shrunken to its smallest diameter; then the adhesions to the circumference of the ovaries are put on the stretch, which during the congestive stage would be lax from the swelling of the ovary itself. An ovary with a pathologically hardened tunica albuginea, which, when the pelvis is filled with blood, has the vascular tissue in its interior thoroughly pressed upward, but when this physiological hyperemia subsides during the trough of the wave, and the tissues shrink, this hard surface bends inward and the surface of the ovary is put on the strain. As I have shown in other papers, this necessarily must produce pain, for if there is one law in pathology it is that, without tension there can be no pain. The simplest of all inflamed ovaries, or tubes, or other inflammations about the pelvis, which give pain just before menstruation, are made far more intelligible than they were in the old-time way, when we knew that there was simply a congestion without knowing how it was produced. These are some of the riddles that this law explains, to a man who has little or nothing to do with major surgery. But for the laparotomist this law is of more value than almost any other. It teaches him never to operate just before a period, when he can possibly avoid it. It also explains to us why it is menstruation nearly always follows the removal of the appendages. It also explains that rather rare accident, traumatic hematocele, which follows four or five days after a laparotomy is done. But these are more than "twice-told tales" to most of my audience. The one to whom, it seems to me, this subject is of more importance than to any other is the general practitioner. No matter what branch he may be in, if he has a troublesome symptom, which recurs regularly at any particular point of the cycle of the menstrual wave, his attention should at once be attracted to the pelvis. There is not a functionating organ in the body which is not deranged by the reflex wave when the pelvis is in such condition as not to allow it to escape freely. Let us consider a few of these symptoms in order:

Indigestions are the commonest associations of pelvic mischief, so much so that I long ago made this statement, "Show me ten women with habitually bad stomachs and I will show you nine who have pelvic trouble." It is a rare thing to have a gynecological case of metritis, a tear of any description, who has a really strong digestion. The constipation of these cases is proverbial, but the indigestions even to the extent of nausea and vomiting, are old, old stories to all of you gynecologists. I have had in my experience not less than three cases, diagnosticated by first class general practitioners as ulcers of the stomach, which when properly investigated showed subinvolutions, lacerations and general pelvic disease, all of whose stomachs promptly got well when the pelvic trouble was corrected. Sometimes the indigestion is worse at the crest of the wave, in other cases it is aggravated at the trough of the wave by the necessary anemia of the sympathetic plexi. The only point is to see if the occurrence of the attacks is at any one particular point in the circle, and whenever that is the case one is very much to blame if he does not at once suspect the pelvis being at fault.

Hepatic symptoms are very commonly produced in this same way. In fact, I have seen three or four cases of reputed gall-stones, cured absolutely by righting the condition of the pelvis. Whenever you have a patient, where you cannot find a gross lesion about the gall-bladder or liver, who has these recurrent attacks, that do not go on to jaundice, the pelvis is, by all means, to be examined. I have relieved three patients, in the last few years, of all symptoms of gall-stones, by doing nothing but curetting the uterus or sewing up a tear.

I have seen forms of Bright's disease very much exaggerated at certain points of this wave. I have had two cases of intermittent glycosuria, which were undoubtedly a sequel of menstrual headaches. The sugar would appear about the time the headache was at its worst, would increase until about the time the headache ceased, and then it would take about a week to fully clear up, to be repeated at the next menstrual epoch, but without a trace of sugar in the interval. Both these cases were absolutely cured by bringing on the artificial menopause. This is produced you readily see, by the old theory of pressure in the floor of the fourth ventricle by the reflex wave. While on the kidney I am lead to speak of a reason the general surgeon ought to have this wave at his finger tips, and I hope you gynecologists will listen closely to the report of the following case. I have a patient, sent me from the Northwest, who had her ovaries removed a year ago. On careful examination of her I found the pain started always on the right side, has been there four or five years, recurrent attacks at intervals of four or five days, running up the right side, along the region of the ureter. These attacks would occur at intervals of three or four days to a week. After suffering from them for three years, somebody removed the

ovaries. Since then the attacks have been worse than ever. On examining her a few days ago, I found she not only had a stricture of the urethra but a badly contracted bladder with decided inflammation of the mouth of the ureter, slight amount of pus in the urine with a number of scales from the bladder, pelvis of the kidney and ureter. All that was needed to have avoided this blunder, was simply to watch the attacks with reference to the Stephenson wave. Instead of recurring regularly every twenty-eight days, as they would have done if due to pelvic or ovarian mischief, they recurred in four, five or six days. And this is the one point that I wish this paper to accentuate. Whenever there is pelvic mischief, even though it may be a reflex pain in some other organ, *that pain* returns regularly at some particular point of the menstrual cycle. Many sins against the ovaries would be avoided if this simple little rule were watched by everyone.

Before leaving the urine, one other point, that is now being worked out by a friend of mine, is that the menstrual wave undoubtedly has a great deal to do with the pathological metabolism of the body. Just how much, I cannot state to-day, as the experiments are not yet complete. But enough has been found out to make it certain that it undoubtedly aggravates all of these cases presenting the xanthin compounds.

Its influence on the heart and lungs has been recognized since the beginning of the world. The hysterical heart, the fainting spells, are as old almost as any other knowledge given us by the Egyptians. The dyspneas associated with it and the vicarious menstruations through the lungs are equally well known. Its influence on the thyroid and heart combined, in the Basedow's disease, are things of rather common knowledge. Many cases of Basedow's disease I have been able to modify very materially, and absolutely to cure a few, by correcting pelvic conditions, but I always give the prognosis in proportion to the amount of disturbance caused in one particular part of the wave. It is generally the congestive side of it that does the most harm. I frequently have noticed, in these cases of Basedow's disease, that the pulse is much more rapid, the thyroid more distended, and the ocular stare more exaggerated just before the flow begins. Where you can find a chronic metritis or an old tear associated with these clinical symptoms, you may confidently promise your patient a certain amount of alleviation of symptoms by ridding her of the pelvicmischief.

Loss of voice has been one of the most interesting subjects that I have studied in this connection. One patient I remember told me that she could tell to the minute when her menstruation would come on simply by the power to speak. For years she had been in the habit of losing her voice just at the beginning of the congestive stage. Sometimes she would have to whisper for several months at a time, but generally the control of the vocal cords would return with the first flow. This case had been treated for years by every imaginable kind of specialist, gynecologic, laryngologic, pulmonary, etc. I found one ovary filled with pus and the opposite tube irreparably damaged. It has now been two years since the artificial menopause was brought on and the voice has never been lost since. In a debate we had on this subject, winter before last, the aurists and oculists brought out some very clear cases of tinnitus aurium, deafness, ambliopias, retinal hemorrhages, choked disks, etc., etc., which were simply inexplicable without a thorough knowledge of the menstrual wave. Some of them were caused by the crest and some by the anemic side of the wave. But to this they were undoubtedly due. Vicarious menstruations from the nose are very common, and in conjunction with the rhinologists I have cured a half dozen or so. In every one I found a pelvic lesion, and the outflow was caused simply by the rebound pressure from the hardened tissue at the site of its wonted outlet.

Epilepsies and insanities, mental derangements of every description, which have regular periodic returns, should be studied very, very carefully before any operation is done. My rule is never to touch one of these cases until I have had her under my care three or four months and am satisfied of a regular periodic return of the symptoms at some particular part of the wave. My experience is that it is the crest of the wave that does the mischief. By this careful study I have been able to cure four or five cases. In one, a most marked case, that I had watched for five months and was absolutely certain that the menstrual wave was the cause of the trouble, I found a large, tender ovary associated with a little childish uterus in a well-developed young woman of twenty-five years. When I first saw her the mental aberration would last the menstrual week. In the intervals she would be about as usual. But during the winter of 1893 I found the deranged condition was lengthening out until the attacks were almost merged into each other, so there was scarcely a week of a sane interval and she was rapidly approaching a complete condition of dementia. The operation was done, and, strange

to say, from the moment of awakening from the anesthetic there has never been a return of the old symptoms. In this field, though, you must be the most careful of all. Enough cases have been operated upon now to pretty well test the relationship between pelvic diseases and insanity. By careful statistics from all over the country, particularly from the Toledo Insane Asylum, it has been found that about five per cent. of female lunatics are so from pelvic causes. But we must remember that it is only about five per cent. and that the other ninety-five per cent. are nothing but lesions of the brain itself, and we must not be trapped into removing the ovaries of these people, unless it is to save life. Of course, they may have ovarian cysts, pyosalpinx and the like, and whenever we can find such conditions, they have as good a right to relief as anyone else, but we cannot expect to cure the mental condition of any more than five per cent. of the whole.

There are many other things I would like to speak of, for, in fact, I know no subject which would be more fruitful and bring out more interesting points for a general debate for a whole morning than the complications the menstrual wave produces when it goes awry. Not only the gynecologist but especially the general practitioner should have the laws of this wave at his very finger tips, for there is no one thing that is capable of more widespread and varied mischief. In handling the menopause is the time when we most need this thorough knowledge. But I have already consumed too much of your time, and for my beliefs about it I will have to refer you to the Transactions of your own State Society for February, 1894. And I cannot have a better close for this paper than to repeat what I have said before, regarding the application of Professor Stephenson's theory, that "its benefits to the modern medical man, in the elaboration of these feigned diseases, has been surpassed by nothing in modern days, and equaled in its benefit to our calling only by Harvey's immortal discovery."

THE many friends of Sir William Priestley (who came to the International Medical Congress at Washington, as Dr. Wm. Priestley) will be glad to know that he has been returned to Parliament for a Scotch seat. He is between sixty and seventy years of age, was Sir James Simpson's favorite pupil and after gaining distinction in Edinburgh, went to London in 1850. He married a daughter of Dr. Robt. Chambers, author of "Vestiges of Creation."

Sir William was knighted at the Queen's jubilee, and will probably receive a baronetcy. He is a great nephew of Joseph Priestley, the discoverer of oxygen.

CLINICAL MEMORANDUM.

TRAUMATIC HEMORRHAGE IN THE CENTRUM OVALE BENEATH THE LEFT ANGULAR GYRUS.

BY J. T. ESKRIDGE, M.D.
OF DENVER, COL.;
NEUROLOGIST TO THE ARAPAHOE COUNTY AND ST. LUKE'S HOSPITALS,
AND
E. J. A. ROGERS, M.D.,
OF DENVER, COL.;
PROFESSOR OF SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF DENVER; SURGEON TO THE ARAPAHOE COUNTY AND ST. LUKE'S HOSPITALS; CONSULTING SURGEON TO THE STATE INSANE ASYLUM.

IN the report of this case of aphasia, and in each of those which are to follow, the history of the case, the results of the examination, remarks on the diagnosis and points of surgical interest will be given. A detailed account of the rather elaborate plan pursued in investigating the different forms of aphasia will be stated in full without any apology for the amount of space consumed, as it is believed the interesting features presented by each case will justify the careful study which one of us has endeavored to devote especially to the character of the speech disturbance.

The plan followed in the study of the aphasia, which includes thirty subheadings, will be given but once, and each subheading will subsequently be referred to by number.

After this series of cases of aphasia have been reported the points of interest, in each case will be discussed in a subsequent paper and published in this journal.

CASE I.—*History, Examination, and Diagnosis.*—William D., colored, aged twenty-three years, single, waiter by occupation, was admitted into St. Luke's Hospital, June 16, 1895. The family history is unimportant. He was always in good health up to a short time ago. He has drunk a great deal, but denies syphilis, although he has suffered from gonorrhea a number of times, and has indulged in venery to excess. Early in March, 1895, while in a fight he fell and broke both bones of his right leg just above the ankle. He was taken to the County Hospital, and was under the care of the attending surgeon, Dr. Rogers. After he had been there about two weeks he was attacked by another patient who struck him on the head, just above the right eye, with a chair, and felled to the ground. He was unconscious from the blow only a few hours. After recovering consciousness he suffered from pain in the head and felt dizzy for a week or more, but two weeks later he was able to return to his work. He made no complaint except that when he blew his nose he experienced pain in his right eye. He continued at his work, feeling quiet well, until June 13, 1895. On the morning of that day he complained of headache, but performed his duties as waiter until about 5 P.M., when he was found in the yard, in the rear of the house, lying apparently asleep. When aroused he placed his hand to his head, moaned, said something, but "his words were so confused" that his uncle was not able to understand

him. After a time he was found wandering about the building, and apparently did not know what he was doing. He was taken home and put in bed. He was very restless, seemed dazed, semi-conscious, talked incoherently, refused food, but drank milk and soups when they were offered him. He remained in about this condition during the next three days. He was removed to St. Luke's Hospital on June 16th, at 9 P.M. I saw him an hour later, and found him lying in bed apparently asleep, and when he was undisturbed he did not complain. On arousing him and asking him if he had headache he replied, "Yes," and placed his hand over the entire front of his head, indicating the seat of pain. As well as I could determine from his answers to my questions, the pain was limited to the front of the head, but felt on both sides. He seemed to be semi-conscious, but the blurred consciousness was complicated with a sensory aphasia. He seemed to understand most of what was said to him, but in answering questions he not infrequently used wrong words and apparently did not perceive his mistakes. After he was aroused he was quite restless, moaned considerably, and the forehead was corrugated, indicative of pain.

There was no apparent paresis or paralysis of any muscles of the legs, arms, or face. It was impossible to test accurately the strength of his muscles on account of his inability to concentrate his mind, I could not attract his attention for more than a moment at a time, and as soon as I left him alone he relapsed into a stuporous condition. He registered, however, with the right hand fifty, and with the left forty on the dynamometer, but he only accomplished this on urging him in loud tones to press hard. The tongue was protruded in the median line. Reflexes: knee-jerks were normal; ankle-clonus and plantar reflexes were absent; tendo-Achillis, normal; cremaster and lower abdominal reflexes were absent. Epigastric, R. present; L. absent. Deep reflexes of the arms were about normal. Masseters absent. Sensation seemed to be blunted over the right side, as a pin prick on this side did not attract his attention, or cause him to wince as it did when he was pricked on the left side. On first testing vision he was apparently blinded on the right side of each eye, but this could not be confirmed by subsequent tests, on account of his blunted mental condition. All the internal and external ocular muscles seemed to act normaliy, pupils contracting to light and accommodation readily. Both optic disks were very small, looked pale, and their appearance was suspicious of beginning atrophy; the vessels, especially the arteries, appearing smaller than normal. No exudate could be observed on either disk. I was unable to test the condition of the other special senses on accout of his blunted mental state.

On endeavoring to test the condition of the aphasia I asked him if he could hear the watch, and he said, "That is a beer." I tried him again, and he said, "That is another beer." When I touched him on the right side I asked him if he could feel me, he said, "I cannot hear," meaning that he could not feel. I asked him if he felt me touch him on the left side, and he answered promptly, "Yes, I can see it." On the left side he seemed to distinguish readily between hot and cold substances, but his words were so confused that it was impossible to make out what he said. The whole examination, especially in regard to the special and general sensory phenomena, was very unsatisfactory. The temperature in the right axilla was 99°; left 99.4°; pulse 48, not very full and rather poorly sustained; respiration 17 and regular, When left alone while he was apparently asleep, or in a stuporous condition, sighing respiration would occasionally occur, and he would moan and rub his head as if in pain. During the night he was quite restless and required rather large doses of cannabis indica to secure any rest at all. His temperature was registered in each axilla every three hours during the night, and was found nearly normal or slightly subnormal, and about the same in each axilla. The next morning there was a slight retraction of the head and some rigidity of the posterior cervical muscles. The ears were carefully examined but no discharge or evidence of disease was found. On shaving the head no depression of bone was detected. At noon he registered on the dynamometer R. 132, L. 128. He remained in about the same condition during the entire day, and at 6 P.M. the head seemed to be a little more retracted than it was in the morning. On my endeavoring to bring it forward it evidently gave him pain. The right side of the face, especially around the mouth, was a little paretic; the tongue was protruded in the median line. The deep reflexes were about normal, while the superficial were abolished on the right side and present on the left. On retesting for hemianopsia I was unable to verify my observations of the night before, but there was perceptible blunting of sensation throughout the entire right side. During the following night he rested quietly with twenty minims of the normal liquid of cannabis indica every hour.

From the time that the patient had been admitted into the hospital, on the evening of June 16th, until the morning of the 18th, a careful record of the pulse, respiration, bilateral axillary temperature, and all other symptoms likely to aid in arriving at a diagnosis had been made every three hours. On the evening of his admission, the temperature in the left axilla was about 1° F. above normal, and ½ above normal in the right; the pulse was 48, with fair volume, but easily compressed; respiration was 17, regular, except an occasional sigh, apparently on account of pain. It was thought that the slight elevation of temperature might have been caused by the jolting in removing him from his lodging-house to the hospital. Three hours later, the temperature had fallen .6° in the left axilla, but remained about the same in the right, so that it was a little higher on the right than on the left side. The pulse had risen from 48 to 55, and respiration remained about the same. From 2 A.M. of the 17th to 6 P.M. of that day, the temperature was practically normal and about the same in each axilla; the pulse varied from 48 to 58, and respiration from 16 to 18. Neither the pulse nor respiration changed in character, but the patient was gradually becoming more stuporous. At noon of the 17th, after the head had been carefully shaved and dried, the surface temperature of each side of the head in the frontal and parietal regions were carefully registered

by myself. The thermometers were allowed to remain in position from ten to fifteen minutes, or three minutes after the mercury ceased to rise. Two thermometers were used, and the temperature over corresponding portions of the head was taken at the same time. Lateral frontal. R. 96.5°; L. 97°. Parietal: R. 96.8°; L. 97.2°. Lest there should be some difference in the thermometers, these were now reversed and the temperatures again recorded, with the following results: Lateral frontal: R. 96.4°; L. 97°. Parietal: R. 96.8°; L. 97.2°.

At 6 P.M. of the same evening (June 17) the temperature was: R. axilla 99.2°; L. 98.4°; P. 52; R. 18. At 10 P.M., temp. in R. axilla, 98.5°; L. 98.4°; P. 50; R. 16. He was very restless, and the stupor was apappearently increasing.

At 1 A.M. of the 18th, temp. R. axilla 99.5°; L. 98.5°; P. 52; R. 16. At 4 A.M., temp. R. axilla 96.5°; L. 95.5; P. 52; R. 16. At 7 A.M., temp. R. axilla 96.8°; L. 96.6°; pulse and respiration the same. At 8.30 A.M., temp. R. axilla 98.6°; L. 98.4°; P. 48; R. 18, The patient was in a more stuporous and apathetic condition than at my visit the evening before, and it became evident that unless something surgically could be done for his relief, death would soon result.

The condition of the optic disks had not perceptibly changed since I first saw him; there was no paresis or paralysis of any muscles; the ability to recognize a pin prick throughout the entire right side was almost entirely lost, and response to irritation of the left side, owing to the increasing stupor, was becoming lessened; he could hear and seemed to understand, when aroused, many things that were said to him, but when he attempted to answer even simple questions, which it was difficult to arouse him sufficiently to do; his words, although articulated distinctly, had no meaning as they were jumbled together in a confusing manner.

My first endeavor, before recommending a surgical operation, was to determine, if possible, the character of the brain lesion, and next to locate it.

The head injury, received some three months before, taken in connection with his history for the past five days since the onset of the acute symptoms, indicated that within the brain substance some subacute or chronic process had been going on, and that this had resulted in rather extensive destruction of brain tissue.

Was it abscess, encephalitis, or hemorrhage? The symptoms of injury to the brain of traumatic origin, sufficient to give rise to decided disturbance, came on immediately after the receipt of the trauma; those that result from inflammation are not usually apparent before the second to the fourth day; while those of abscess rarely appear before the second or third week, and may be delayed much longer. Hemorrhage into the brain substance may occur immediately after the head injury, several days, or even months subsequently to it. Delayed or late hemorrhage into the brain substance from traumatism probably only takes place as a result of previous encephalitis and softening. Sudden symptoms of brain lesions may occur in syphilitic subjects weeks or months after an injury to the head, and may be due to thrombosis of a vessel or gumma of the membranes. It is a well-known fact that traumata to the head frequently light up latent syphilis of the brain. Extensive meningeal lesions, especially of syphilitic origin, rarely come on suddenly. They are preceded by violent headache and are attended by a rise of temperature, and frequently by twisting of the facial muscles, or general convulsions. Syphilis affects the large arteries at the base most, and a thrombotic occlusion of a vessel under such circumstances is usually attended by motor aphasia or hemiplegia, or by both.

In the patient whose case is under consideration, the unconsciousness which immediately followed the injury, and lasted only about three hours, could be accounted for on the theory of concussion of the brain from the force of the blow. The symptoms of cerebral disturbance, consisting of slight headache and dizziness, lasting for about two weeks, must have been insignificant, as he did not call the attention of the attending surgeon to them. In the patient's semi-conscious condition, when I saw him, it was impossible to learn whether the headache and dizziness were worse immediately after the receipt of the blow to the head or two or three days subsequently to it. Had these symptoms developed a few days after the injury, they would have pointed to encephalitis. But had a slight encephalitis occurred, this might have been followed by hemorrhage or suppuration.

The head injury attended by an open scalp wound, the slight cerebral disturbance for two weeks, the latent period of nearly three months duration during which he was able to walk, although he did not feel entirely himself, especially in regard to his head, the sudden development of profound brain symptoms, and the vacillating temperature, varying from one degree Fah. above normal to two degrees below, with slow pulse and respiration, certainly pointed very strongly to abscess of the brain. The mental apathy, with power to comprehend for a moment when aroused, but inability to maintain mental concentration for more than a few moments at a time, is found most typically illustrated in abscess of the brain, The patient was a colored man, and the peculiar dusky yellowish hue, so often seen in cases of abscess of the brain, could not have been detected in him had it been present.

The history and many of the symptoms of the case were more in favor of cerebral suppuration than of hemorrhage into the brain substance. There were, however, an absence of certain symptoms that one expects to find present in the terminal period of chronic abscess of the brain. After this stage of chronic abscess of the brain is reached, the temperature begins to rise as the stupor and coma deepen. In this patient, the temperature was nearly two degrees Fah. lower than it had been thirty-six hours before, although stupor was more marked, and a fatal termination seemed to be threatened. With the rise of temperature in the terminal stage of abscess of the brain, the pulse and respiration increase in frequency in proportion to the destruction of brain function.

The behavior of the temperature, pulse, and respiration, with the increasing stupor in this patient, made me doubt

the existence of an abscess, and suspect an encephalitis that had resulted in softening, If this condition existed, I reasoned that hemorrhage occurred into the focus of softening on the 13th, the time when the acute symptoms suddenly developed, and that there had been a recurrence of the hemorrhage on the morning of the 18th.

I confessed myself at the time unable to make more than a problematical diagnosis. I was inclined to regard the case as one of encephalitis with subsequent hemorrhage, although, as I told Dr. Rogers just before the operation, I would not be surprised to find an abscess. Had the patient's condition warranted delay in a surgical procedure, it is probable that a positive diagnosis could have been made.

The second problem to determine was in relation to the location of the lesion. This was not as difficult as at first it might seem. The patient was known to be right-handed, therefore the faculty of speech would naturally be located on the left side of the brain. There was a condition of sensory aphasia, without disturbance of motility, hearing, or motor speech, therefore the lesions must be on the left side and posterior to the temporal convolutions. Although his mental condition was such as to make it impossible to determine the exact character of the speech defect, the visual fields, or other symptoms, it was quite evident that the lesion was in the region of the angular gyrus or posterior to it. The anesthesia throughout the entire right side, without hemiplegia, but with sensory aphasia, seemed to point quite definitely to the lesion being an extensive one in the centrum ovale of the parieto-occipital region, in such a position as to involve the fibers from the angular gyrus, the inferior parietal lobule, and probably those from the occipital lobe also.

Dr. E. J. A. Rogers, under whose care the patient had been while in the Arapahoe County Hospital, was requested to see the patient with me. On carefully studying the symptoms together, surgical means seemed to offer the only hope of relief. As the patient's condition was desperate and becoming hourly worse, he decided to operate at once, and in this opinion I concurred.

The operation was begun at 10.30 A.M. on June 18th, chloroform being the anesthetic used. The pulse before beginning the operation was 48; upon opening the skull it increased to 70, and upon the completion of the operation was 96.

The skull was opened by a ¾-inch trephine at a point about 2½ inches backward and upward from the external meatus,[1] and then enlarged by a rongeur-forceps. Pulsation was absent in the exposed area, but the dura bulged and showed great tension from internal pressure. The dura was divided and the brain explored by a canula, first forward and then inward without result. Upon exploring backward into the anterior portion of the occipital lobe, a mass of old clotted blood was found with a definite capsular limit. This area was washed out and quite a quantity of *debris* removed. No pus or other indication of inflammation was discovered. The wound was closed without drainage. Upon warming the patient in bed the pulse immediately began to fall and steadily continued to do so, the patient remaining in a profound coma and symptoms indicating pressure becoming more and more marked.

On the day following the condition continued growing worse, At 5 P.M. the temperature in the left axilla was 99.2°; the right 98.8; pulse varied from 44 to 48, and respiration was irregular and sighing from 8 to 12 per minute.

The condition of the patient seemed so hopeless that we deemed it best to again explore and try to relieve him. At 8 P.M. the sutures were removed and the cranial opening much enlarged downward and backward, and a sharp trochar with canula was then forced through the tentorium cerebelli, and the posterior fossa explored without result. The area discovered yesterday being now thoroughly uncovered was freely laid open and washed out and a much larger quantity of clots and *debris* removed. Drainage was left and the wound dressed. The patient again sank into the same state as before, but improvement was constant and regular from this time on, the results showing, I believe without question, that his sufferings were due to pressure produced in the area relieved.

After the second operation the pulse rose from 44 to 96; respiration from 12 to 22; the temperature remained nearly normal for about twelve hours. After this, the temperature rose from 1° to 1.5° above normal, then it dropped to normal a few hours later. The pulse varied from 92 to 98 for about thirty-six hours after the second operation, when it fell to 66 or 70 while he was asleep, and varied from 78 to 84 during his waking hours, the most of which time he was restless. Respiration did not fall below 17 or rise above 24 after the second operation. While no apparent shock followed the first operation, he seemed to be very weak after the second, and it was a surprise to Dr. Rogers, the resident physicians, and myself to find him alive the morning of June 20th. From June 19th to the 24th the record is uneventful. During this time he took considerable liquid nourishment, appeared profoundly unconscious, and was quite noisy, especially during the night when he would frequently yell at the top of his voice. He was given twenty minims of the normal liquid of cannabis indica every hour while he was noisy, usually with the effect to quiet him and make him sleep, after the second or third dose.

On the 24th, his pulse was observed to be 52 when he was asleep, but it arose to 75 on his awaking and becoming restless. It was noted that a pin-prick on the right side caused him to wince. From 1 A.M. to 6 A.M. of June 25th, he was very noisy and moaned continually, and at 7 A.M. the pulse registered only 42, the lowest it had been since the second operation. There were no other indications of increased cerebral pressure. After a free bowel movement the pulse registered 72 and he was partially conscious.

During the next two weeks he improved steadily, and by the end of this time he was quite rational and able to sit up an hour or two each day.

Examination July 7, 1895: There is no paresis or

[1] Dr. Rogers gets at this in a roundabout way. By actual measurement the point was 1½ inches above the external auditory meatus and the same distance posterior to it.

paralysis of any muscles. Dyn. R. 104; L. 130. Deep reflexes are nearly normal and about the same on each side of the body. The superficial reflexes are lessened on the right side, but normal on the left. Temperature and pain sensations apparently about equal on each side; tactile slightly lessened on the right; posture and pressure still more impaired, and muscular and localization sensations lessened to the greatest extent on the right side. Smell: He can detect an odor with either nostril, but does not seem able to name it. Hearing: Watch, R. ⅓; L. ⅔. Impossible to test him with the tuning fork as he becomes confused. Eyes: Central vision apparently nearly normal; the external ocular muscles act well, and pupils respond to light and accommodation. Right bilateral homonymous hemianopsia apparently complete. No Wernicke pupillary phenomenon. Sensory aphasia is quite well marked, but he is fatigued and the examination has to be postponed.

On July 8th, I examined into his condition of aphasia. The plan that I am in the habit of using in examining these cases is elaborated from the one suggested by Dr. M. Allen Starr.[1]

1. The power to recognize objects seen, heard, felt, tasted, smelt, and their uses.

2. The power to recall the spoken names of objects seen, heard, felt, tasted, and smelt.

3. The power to understand sounds other than speech.

4. The power to understand speech and music.

5. The power to call to mind objects named and point them out at request.

6. If word-deaf, can he recognize his own name when it is spoken?

7. The power to recognize a word spelled aloud.

8. The power to call up mentally the sound of a note, figure, letter, or word.

The examination thus far will test the various sensory areas, but more especially the auditory and the association tracts between the different sensory areas connected with speech.

9. The power to recognize letters, figures, notes, and colors seen.

10. The power to understand printed and written words seen.

11. The power to read printing, writing, and music aloud and inaudibly, and to understand what he reads.

12. The power to recall objects, the names of which are seen.

13. The power to write voluntarily.

14. The power to write at dictation.

15. The power to copy, and the manner of copying, printing, and writing.

16. The power to write the name of objects seen, heard, felt, tasted, and smelt.

17. The power to read aloud and inaudibly, and to understand what has been written.

18. The power to write his name and the ability to read it when written by himself and by another person, or when it is printed.

19. The power to recognize a letter by tracing it with the index finger or with a pencil, the movements being guided by another.

20. The power to call up mentally the appearance of an object, a figure, note, letter, or word, when word-blind.

These additional tests will aid in determining the condition of the visual word-memories in the angular gyrus, and the connection between this area and the surrounding sensory and motor areas:

21. The power to speak voluntarily, and, if impaired or lost, the character of the defect.

22. The power to repeat words after another.

23. Does the patient recognize his mistakes in speaking and writing, and can he correct them?

24. Can the patient think in speech (propositionize)?

25. Is there any special difficulty in the use of nouns, verbs, or other parts of speech?

26. The power to understand pantomime or gesture expression.

27. The power to employ intelligently gesture in expression.

28. The power to read figures and to calculate.

29. The power to count both money and in numbers.

30. The power to play a game of cards or other games.

In testing his ability to recognize objects seen, it was found that he could recognize only a few, and those were of the most familiar character, such as a pencil, book, or knife. If these objects were presented to him in rapid succession, he would become confused. At times he would recognize a watch, and at other times he would not. By the senses of hearing, tasting, and smelling, his ability to recognize was about as good as it was with vision. By the sense of touch he was unable to recognize a single object with the right hand, He could recognize a few objects by feeling them slowly and carefully with the left hand, but the process was slow and much below the normal. For all those objects that were recognized by him he had no difficulty in telling their use, but, as we should expect, he had no idea of the use of unrecognized objects.

Apraxia is a term employed to express the loss of memory for the use of things. It has been used to denote, more especially, the loss of visual memories, as soul blindness, object blindness, etc., but it is equally expressive when used to denote the loss of any of the other special sense memories.

The patient then was suffering from partial apraxia for memories of all the special senses except tactile, but for those of this sense the apraxia was complete on the right side and partial on the left.

In testing his power to recall the spoken names of objects seen, heard, felt, tasted, and smelt, the defect in this appeared to be similar to that found in testing his ability to recognize objects. With all senses, except tactile, he could recall the names only of the most familiar objects, but with tactile sense he seemed to gain no definite idea of an object with the right hand, and but little with the left.

He understood speech and sounds other than speech perfectly.

[1] *Medical Record*, October 2, 1888, p. 497, and *Brain*, vol. xii, 1889, p. 95.

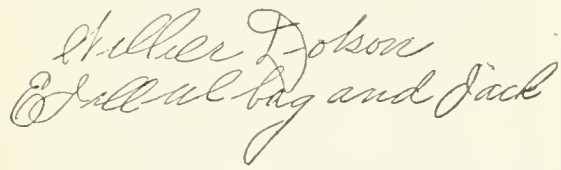
He had never known anything of music.

He experienced little difficulty in calling to mind objects named, and pointed them out when requested.

On carefully testing for auditory speech defects none were found,

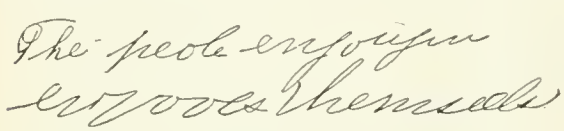
On testing for 9, 10, 11, 12, of the plan followed in examining an aphasic, he made a complete failure.

On testing for 13, the power to write voluntarily, he wrote

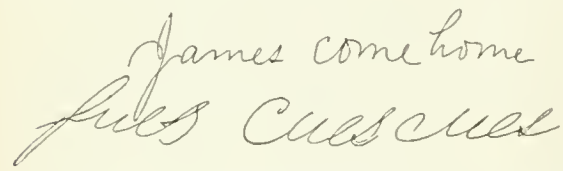


Meaning to write William Dotson (his name), but the other has no meaning.

On dictating for him to write "The people enjoyed themselves," he wrote

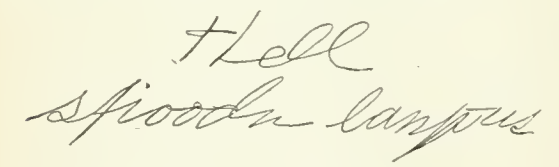


I wrote and requested him to copy, "James, come home," and he wrote



Unfortunately I failed to test his ability to copy printing.

After he had learned to recognize and name "bell," "spoon," and "lamp," he was asked to write their names, and No. 4 is the result, in the order given below.



17 was a failure, except for efforts under 18.

Under 18 he wrote (No. 1), getting the last part of his name correct, but "William" is wrong, although the first five letters are correct. He was able to read his name immediately after writing it, but the next day he failed to decipher it. He could not read his name when it was written by another person nor when it was printed.

19. Occasionally he could recognize a letter which his index finger was made to trace.

20. He could mentaliy call up the appearance of some objects, most figures and letters, and a number of words. He knew no notes.

The answers to 21 and 22 were perfect. 23. He made no mistakes in speaking. He seemed to recognize his mistakes in writing, at least, some of them, but he was powerless to correct them, and usually made a greater error when he attempted to improve his writing.

The answers to 24, 25, 26, and 27 were perfect.

28. He could read a few figures and add anything below ten, but nothing above this, neither could he subtract or divide. Before his injury he had no difficulty in subtracting or dividing.

29. He could count mentally from one to any number, but he could not money.

30. He could not play a game of cards.

The next day, July 9th, the patient went to the telephone, called for a number, and when the party answered and asked his name, he was unable to give it. He turned to the nurse, who was standing near and said, "Who am I? What's my name?"

On July 12th, the condition of apraxia proper, had entirely passed away. He had no difficulty in recognizing an object and its use, but often failed to name the most familiar objects, even after the name of the object had been given him only a few moments before. On showing him an object and calling it by various names, he made no mistake in recognizing its name when it was spoken. He was at that time suffering from a condition of verbal amnesia.

July 13th, he was asked to write to twenty. He wrote the numerals from 1 to 10, inclusive, in their regular order, omitting 11 and 12, wrote from 13 to 19 correctly, but on beginning a new line he started at 12 and wrote to 16, omitted 17, then began at 18 and wrote to 21 correctly. After writing the above figures he said that he knew what they were, but could not recall the names of them. On questioning him I found that he could give the names of a few numbers that he had just written. July 14th, he went out in the morning for a walk without permission, was in the sun for an hour, returned looking exhausted. I happened to be in the hospital about the time that he returned from his walk, and on testing his ability to name things, he showed almost complete amnesia for the name of everything, no matter how familiar it was. He manifested nearly as greatly a degree of apraxia as was detected on July 8th.

He was ordered to bed and the nurse was requested to see that he did not leave his ward again without permission. During the remainder of the day he was physically and mentally exhausted, and suffered some from headache, or a dull heavy feeling in his head. He slept well during the night. July 15th, 9.30 A.M.; temperature, axillary, R., 98.2°; L., 98° F.; P., 62; R., 18. Suffering from severe pain in the head, especially in region of the operation. 9.30 A.M., felt miserable and vomited. 10 A.M., vomited again, headache agonizing. At 11.20 A.M., vomited the third time. Temperature, axillary, R., 101.6°; L., 101.8° F.; P., 70; R., 26. Bowels were freely opened with calomel. Slept one hour. 1.30 P.M., vomited again. During the remainder of the day he vomited every hour or two; headache was severe, and he was delirious much of the time; an ice poultice was kept constantly applied to the head, and he was given full doses of cannabis indica for the relief of pain. At 5 P.M. Temperature, axillary, R., 101.2°; L., 100.8° F.;

P., 70; R., 26. His head was dressed, and as there was considerable prominence at the site of the operation, the wound was reopened, and a small quantity of liquid blood was let out. At 12.30 A.M. of the 16th, he was still vomiting, delirious, and suffering from head pain. Temperature, axillary, R., 101.6°; L., 101.2° F.; P., 72; R., 28. During the 14th and 15th his urine had to be drawn. At 8.20 A.M. his temperature, pulse, and respiration were about normal, but he was suffering greatly from headache. During the afternoon the post-cervical muscles were quite stiff, and on my attempting to bring his head forward it gave him considerable pain. On the morning of July 17th he seemed as well as he had been before the relapse, except a slight depression.

July 18th he was asked to write a dictation, "All the boys are laughing at me." He wrote, "All boys are faom at me," forming all his letters perfectly. On attempting to write a dictation, "All the girls are laughing at me," he wrote, "All girls are laon at me mel lell wnel attle," still forming his letters perfectly. He could not read a word that he had written.

On the morning of July 20th I requested him to write me in the afternoon how he had been during the day. He spent about an hour in writing, "Dr. Eeley Ia fell in nuy go to dad from "H. DOTSON.
"W."

He could not read a word of what he had written, but said he had intended to write and thought he had written. "Dr. Eskridge, I have been feeling very well to-day. From W. H. Dotson."

On July 23d, his letter was equally illegible, but his own name, Wm. H. Dotson, and his address, Edmond, Kan., were written distinctly. He could read his own name and address, but scarcely another word of his letter.

On July 24th, he wrote my name, his own, and his address perfectly, could read them, and was able to read a few words of his letter besides. It was evident that he recognized his mistakes. He spelt "gioel," scratched it, and wrote "girl." Some sentences were written correctly, *e.g.*, "My girl was to see me." For "but I see that I cannot write correctly," he wrote, "but I seet I aanot were krat." In closing his letter he tried to write, "I hope you will excuse poor writing," he wrote, "I lop you nul esast pool writ," and then signed his name and address in a bold, good hand, every letter well formed, and every word correctly spelled.

Third examination July 24, 1895.

Motility, reflexes, general sensation, and all the special senses, except sight, normal. Sensation was perfect on the right side as it was on the left. The pupils reacted well to light and accommodation, and no changes were noted on examination with the ophthalmoscope. Central vision good, but a little better in the right eye than in the left. The difference in acuity of vision of the two eyes was thought to be accounted for by uncorrected refraction error. Fields: R. of each eye narrowed and amblyopic for objects; L. normal. The condition of complete hemianopsia had passed away. There was no apraxia and he had no difficulty in recalling the names of objects. On testing according to the plan pursued in the examination, from 1 to 8 inclusive, were answered perfectly. From 8 to 20 inclusive, showed a number of mistakes, but they were much less numerous and slighter in degree than on July 8, and he now recognized his mistakes and could often correct many of them by a little effort. Scarcely a letter was written that did not contain an apology for his mistakes. The answers from 21 to 30 inclusive, were perfect.

He continued to improve daily, wrote much better, but still had some difficulty in reading both writing and printing until nearly the last of August.

On the 27th of August Dr. Edward Jackson kindly examined the patient's eyes, and reported as follows:

"The ocular movements and eye grounds are normal. Both eyes present considerable irregular astigmatism, yet with correcting lenses: R. +0.50 cyl. axis 90°, vision = 4/4; L. +0.37 spherical, vision = 4/4 nearly.

"Taken with the hand the fields of vision are: R. normal; L. not positively diminished, but the periphery of the field is noticeably amblyopic as compared with the right, or with the normal of a healthy person."

It will be observed that neither Dr. Jackson nor I detected any "crossed amblyopia," but Dr. Jackson found the left eye slightly amblyopic in the peripheral fields.

MEDICAL PROGRESS.

Idiopathic Fibrinous Bronchitis. — As the result of a clinica study SOKOLOWSKI (*Deutsches Archiv für klinische Medicin*, 1896, B. lvi, H. 5, 6, p. 476) expresses the conclusion that acute fibrinous bronchitis is a disease conforming to the type of a pure infectious process, and of which possibly the staphylococcus aureus and albus act as causes. Typical acute cases are probably uncommon; milder cases are more common, but are frequently overlooked and confounded with bronchial asthma, with which they have a certain clinical relationship. So-called chronic fibrinous bronchitis is an obscure morbid process probably of quite different etiology than the acute disease, with which it has in common only the fibrinous casts of the bronchial tubes, which may occur also in connection with tuberculosis, diseases of the heart, etc. Pulmonary tuberculosis appears to play a very subordinate rôle in the etiology of chronic fibrinous bronchitis.

The Toxicity of the Urine of Epileptics.—As the result of an experimental inquiry MAIRET and BOSC (*Archives de Physiologie*. April, 1896, No. 2, p. 428) have determined that the urine of epileptics possesses in general a low degree of toxicity, which is manifest only after attacks and in the intervals between them. That of urine passed in advance of the paroxysm corresponds with that of normal urine. The increased toxicity observed in the preparoxysmal period is most marked immediately in advance of the attack. The hypotoxicity appears immediately after the attack and is most pronounced in the succeeding hours. The toxicity of epileptic urine, in its action upon all functions except those of the nervous system, corresponds in quality also with that of normal urine. Upon the nervous

system, however, epileptic urine—and especially that of the preparoxysmal period—has more intense convulsive action.

The Influence of Massage upon Absorption through the Veins and Lymphatics. — Kellgren and Colombo (*Archives de Physiologie*, April, 1896, No. 2, p. 462) have determined, by means of an investigation conducted in the laboratories of the Royal College of Physicians of London, and of the Royal College of Surgeons of England, that massage has always a certain and active effect in augmenting the rapidity of absorption of substances injected into tissues and organs susceptible of manipulation. It is inferred that the effect would be the same upon pathologic exudates. The course followed in the process of absorption by the substances injected is through the adjacent lymphatics and the related glands. The absorption of substances injected into the peritoneal cavity takes place not only through the abdominal, but also through the thoracic lymphatics and glands. Petrissage proved more efficient in the absorption of substances injected beneath the skin and into the muscles and joints; and deep effleurage in the absorption of substances injected into the peritoneal cavity. It is believed that the veins also play an important rôle in the absorption of injected substances, and that they are especially active under the influence of massage.

Subacute Anterior Poliomyelitis with Paralysis of the Diaphragm in an Adult. — Grawitz (*Berliner klinische Wochenschrift*, 1896, No. 12, p. 245) has reported the case of a woman, eighteen years old, engaged in knitting bright-colored wool by machinery, who, after several days of general malaise, while nursing her seven-months old infant, complained of severe pain in the head and neck, with difficult movement of the neck and spine. It was not known whether fever was present or not. At the end of three days these symptoms disappeared, and at this time paralysis of the right arm was observed. On the following day the left leg was dragged in walking, and two days later the right leg and left arm also were paretic. Sensibility was in no wise disturbed. Breathing was not interfered with, but on deep inspiration a depression appeared below the ensiform cartilage, and the costal arch was drawn upward. The liver failed to descend in inspiration, but was rather drawn upward. In attempting to bear down, the patient used the abdominal muscles, but not the diaphragm. This latter muscle responded but feebly to strong faradic currents and not at all to the galvanic. The reflexes were very widely abolished. The muscles of the paralyzed parts generally were wasted, and yielded reactions of degeneration. The case is looked upon as one of subacute anterior poliomyelitis in a woman predisposed by protracted lactation at an early period of life, in conjunction with hard work, and exposed to possible intoxication through the handling of bright-colored wools.

THERAPEUTIC NOTES.

Treatment of Alcoholic Cirrhosis of the Liver.—While the lines of treatment to be pursued in cases of alcoholic cirrhosis of the liver are pretty much the same whether the viscus is enlarged or diminished in size the prognosis is much less favorable under the latter than under the former condition. The diet should consist essentially of milk, not less than three quarts being given in the course of the day in divided amounts. Alkaline waters in moderate quantity may be permitted. If the milk is badly digested to each glassful may be added a tablespoonful of the following solution:

℞ Calcium chlorid, . . . 15 grains
Water, ... 3 ounces

Or, with each glass of milk a tablet of the following composition should be taken:

℞ Pancreatin, Pepsin, Sodium bicarbonate, aa . . 3 grains

When the ascites has disappeared and the digestive functions are improved, in the course of from six weeks to four or five months the severity of the regimen may be mitigated, and white meats, green vegetables, and a small amount of farinaceous food permitted, while alcohol in any form, red meat, fat fish, and condiments are to be withheld. When possible, the milk-cure may be conjoined with the raisin-cure. Medicinally potassium iodid may be given in doses of from 7½ to 30 grains, if necessary, for a period of several months. This drug is especially useful if the liver is fatty. When the disease is advanced iodism is to be guarded against, as this condition is attended with an increased probability of hemorrhage. If the enlarged liver is painful, and congestive exacerbations occur, calomel is to be administered—either gr. $\frac{1}{6}$ or gr. $\frac{1}{3}$ every morning for several months, or beginnning with gr. $\frac{3}{4}$ four times the first day, administering gr. $\frac{1}{5}$ four times a day for six days, then intermitting for fifteen days and then resuming as before. Meanwhile, the mouth is to be carefully watched for signs of mercurialism. Local revulsion meets the same indications as calomel. Vesication is to be avoided, as the kidneys are rarely healthy. As a diuretic calomel may be employed in doses of from gr. jss to gr. iij four times a day. A combination of squill, potassium nitrate, and potassium acetate may also be employed, or lithium carbonate with potassium nitrate, or a combination of the powder and the extract of squill. As a purgative, gamboge may be employed, or euonymin with extract of hyoscyamus, or a combination of magnesia with flowers of sulphur. When in spite of diet, diuretics, and purgatives the ascites does not diminish or occasions dyspnea the fluid must be evacuated by puncture, repeated if need be.—*Gaz. Hebd. de Méd. et de Chirurgie*, 1896, No. 28, p. 335.

The Treatment of Diphtheria with Antitoxin.—Blumenfeld (*Wiener klinische Wochenschrift*, 1896, No. 13, p. 223) reports 229 cases of diphtheria treated with the antitoxin in country practice by different physicians with 20 deaths—a mortality of 8.7 per cent. Sixty of the cases were of the severest character and attended with involvement of the larynx. About a third of the cases were of mild type. Of 48 cases, treated during the same period without the antitoxin, 11 terminated fatally—a mortality of 23 per cent. The use of the antitoxin was throughout unattended with unpleasant results.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to The Medical News will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: J. RIDDLE GOFFE, M.D.,

SATURDAY, JUNE 6, 1896.

THE AMERICAN GYNECOLOGICAL SOCIETY.

The American Gynecological Society has reached years of maturity, and at its annual meeting in New York last week, it celebrated its twenty-first anniversary.

The meeting will be remembered for its many interesting features, among which may be mentioned the presence of the famous Parisian surgeon, Dr. Paul Ségond. Not only was everyone charmed with the genial bearing of the visitor, but all were favored with the rare opportunity of seeing him demonstrate, in a variety of cases, his method of operating. As one of the leading advocates of the vaginal route of attack for suppurative disease in the female pelvis, and of the removal of fibroid tumors of the uterus by morcellation, his coming was especially welcome as furnishing the chance for witnessing a demonstration of his procedure. His maxim, in operating, is "See what you cut, and cut what you see." He is extremely methodical and systematic. The distinguishing feature of his method in operating for pus is, that he bisects the uterus anteroposteriorly after clamping the uterine arteries, and drags down the appendages, removing them still attached to either half of the uterus. His operation is peculiarly free from hemorrhage, and exposes itself to only one criticism, which, however, is somewhat questionable, and that is, the desirability of opening the septic uterine cavity as he does, between the very lips of his wound. His method of drawing down a fundus uteri by stepping his forceps one after the other along the tissue, was particularly neat.

Although an ardent advocate of this method of procedure, he not only recognized the limitations of it, in its application to fibroid tumors, but steadily adhered to that principle in the presence of five large fibroid tumors of the uterus, which had been held in waiting for him, and which he absolutely refused to attack by that route, on account of their size.

The scientific work of the meeting showed a decided trend toward conservatism. The preservation of organs formerly sacrificed on slight provocation, was emphasized by the tone of more than one paper. The most striking illustration of this, perhaps, was the paper of Dr. Howard Kelly, in which he advocated attacking an ectopic gestation sac through the vagina and simply draining its contents, without interfering radically with the organs themselves. While advocating conservatism as regards the organs already in the field of gynecology, a commendable spirit was shown in extending this field to cover diseases of the ureter, the vermiform appendix, and the kidney.

The Society was increased by the admission of four new members, but the determination to maintain its high standard of qualification is shown in the fact that three applicants were rejected.

The social features of the meeting were as full of interest and enjoyment as the facilities of the metropolis could furnish, and were highly appreciated by the visiting members.

The Society, by unanimous vote, approved of the memorial to Congress in opposition to the anti-vivisection bill now pending.

THE PATHOLOGICAL INSTITUTE OF THE NEW YORK STATE HOSPITALS.

From a recent address by the newly appointed director of the Pathological Institute of the State Hospitals, Dr. Ira Van Gieson, we learn of the

scope and plan of what promises to be one of the best equipped laboratories in this country. Five thousand square feet of floor space have been secured in the Metropolitan Building, Madison Square East, New York City, and this is now being apportioned into a large general laboratory and demonstration-room, rooms for cell work, for chemistry and physiology, and for hematology, together with a library, director's room, photographic-room, etc.

Although the chief aim of the Institute is to study the physical basis of insanity, it is apparent that the director intends to do this along the lines which have contributed so materially to our knowledge of neurology and general pathology; that is, by investigation of the comparative anatomy and biology of the nervous system, of the physiology, cytology, and cytological chemistry of the nerve-cell, and of bacteriology, especially in its relation to the production of toxemias of the nervous system, as well as by investigations applied directly to reveal the somatic accompaniments of insanity. With this end in view, it is proposed to have among the five permanent associates of the director one who has had special training in hematology, another in biology and embryology of the nervous system, another in physiological chemistry, another in bacteriology, and finally one who is adapted to conduct and plan out work in experimental toxemias and intoxications of the nervous system. Thus the plan of conduct of the work is a broad and liberal one, and insomuch as the problems of mental pathology will be approached in the light of the inferences drawn from all of the subdepartments of neurology and pathology, the output of the laboratory cannot help but materially advance the comprehensiveness of neurology. Moreover, if it fulfills its promise, and if the medical officers of the various State asylums embrace the opportunity which is here given to them to carefully study their obscure and unintelligible cases, the stigma of inactivity and non-productiveness which has been attributed to those who have the care of the insane will be no longer merited. The directors are not unmindful, apparently, that such a venture as the pathological institute, in order to be a success commensurate with the expenditure of such a large amount of money, must needs be in closest touch with the general medical profession and directly conducive to their advantage. With this end in view, it is proposed to furnish opportunity, after the needs of the asylum physicians of the State have been satisfied, for members of the profession to endeavor to interpret whatever vagaries of disease to which they may wish to direct their scientific inquiries, while their labor will be facilitated, and interpretation suggested by those specially skilled in individual departments.

The State Commission in Lunacy has shown commendable perspicacity and wisdom in the selection of New York City as the location for such a laboratory. The advantages to be derived from such location, contrasted with those in any other part of the State, are so apparent as not to need mention. The consolidation act, which has recently made the Greater New York one of the first cities in the world in population, has at the same time enhanced its claims to the distinction of being the chief center of advanced medical and scientific thought on this side of the Atlantic. It stands to reason that a city which supports two great universities, with their modern and aggressive medical departments, as well as four prosperous and mature medical colleges, not to speak of two thriving and progressive post-graduate medical schools, should attract and keep within its confines the most enlightened savants of the age. Where they do their work, there is the center of scientific advance; where they are gathered, therefrom spreads the cosmos of scientific activity. Institutions that aspire to contribute to material science must keep in touch with the great universities and the minds which are gathered within their shades, and must be situated in the centers of medical learning. In these directions it would seem that the Pathological Institute of the New York Hospitals has started right.

ECHOES AND NEWS.

Dr. Daniel Lewis of New York City, has been re-elected president of the New York State Board of Health.

Dr. Gowers of London has been elected a foreign correspondent by the Medical and Surgical Society of Bologna.

The German Ophthalmological Society will hold its next meeting at Heidelberg, August 5th.

IT is rumored that Sir William MacCormac will probably be elected the next president of the Royal College of Surgeons of England, to succeed Mr. Christopher Heath.

UNDER the will of the late Surgeon-general Edward Jacob Forster, his medical library will be donated to the Boston Medical Library.

THE STATE BOARD OF HEALTH OF MASSACHUSETTS has announced that it is now prepared to undertake the bacterial diagnosis of diphtheria, sending out the necessary tubes and reporting back the results to those who send to it cultures for examination. Examination of suspected tuberculous sputum will also be made on request.

ANOTHER victim of "Christian Science" is reported from Booneville, a village near Utica, N. Y. Two weeks ago Mrs. A. gave birth to a daughter. She was treated by Christian Scientists and no physician was called in. Yesterday she died. This is the second case of this kind in Booneville.

DR. THOMAS DUN ENGLISH, of Newark, N. J., the author of "Ben Bolt," graduated from the Medical Department of the University of Pennsylvania in 1840, and now, as an octogenarian, will probably attend the approaching commencement exercises of his alma mater.

THE OHIO STATE BOARD OF MEDICAL REGISTRATION AND EXAMINATION is making a creditable record for faithful and energetic discharge of its duties. It already has before it the vexed question of how far the optician should be permitted to go in fitting glasses as well as other problems of less importance. The matter of recognizing the diplomas, issued by certain colleges within that State, will cause a careful investigation of their methods and general standing as scientific institutions.

IF the press reports are altogether reliable, a system of baby-farming is pursued with great audacity and upon an extensive scale within or near New York City. During the past month one or more waifs have been daily taken to Bellevue by the police. An examination of these has led the authorities there to conclude that many of them come from the same source, but as it is difficult to determine to which department of our municipal government belongs the duty of looking into this species of crime against the innocent, the practice flourishes.

ACCORDING to calculations made from the experience of American railroads for the past twelve years, only one passenger is killed out of every 1,985,153 carried, and only one is injured for every 183,822. A person would have to travel over four million miles before it would come his natural turn to be hurt, or over forty-seven million before he should expect a fatal accident. In other words, a man, unless removed by intercurrent disease, may certainly expect death from accident after 181 years of continuous travel by rail.

THE medical college heretofore known as the Medical Department of the University of Wooster, located at Cleveland, O., has just completed a union with the Ohio Wesleyan University of Delaware, O., becoming the medical department of the latter institution, and will be known in the future as the Cleveland College of Physicians and Surgeons. A very valuable lot, 80 x 120 ft. in size, has been donated to the University upon condition that a medical college building be erected and equipped for laboratory teaching by October, 1897. The building is to cost not less than $50,000, and funds for its erection have already been pledged. The new Cleveland General Hospital is under the exclusive control of the new college for clinical purposes, and with the improved facilities for laboratory teaching afforded by the urgently needed new building, the school will be very fortunately situated for medical teaching. Dr. Charles B. Parker has been elected Dean of the medical school, and Dr. H. W. Rogers has been re-elected Secretary.

THE authorities in India have forbidden the use, by the natives, of the water bottle made of skin for transporting drinking water, and have supplied metal buckets instead. They also require all water to be boiled before being drunk. These precautions are instituted to prevent a return of the virulent epidemic of cholera that prevailed last year.

From *Science* we learn that during the recent session of the National Academy of Sciences a report was prepared with reference to the proposed legislation interfering with the practice of vivisection in the District of Columbia. The report states that physiology must be studied by experimental methods. The physiologist, no less than the physicist and the chemist, can expect the advancement of his science only as the result of carefully planned laboratory work. If this work is interfered with, medical science will continue to advance by means of experiment, for no legislation can affect the position of physiology as an experimental science. But there will be this important difference: The experimenters will be medical practitioners and the victims human beings. That animals must suffer and die for the benefit of mankind is a law of nature, from which we cannot escape if we would. But the suffering, incidental to biological investigations, is trifling in amount and far less than that which is associated with most other uses which man makes of the lower animals for purposes of business or pleasure. The men engaged in the study of physiology are actuated by motives no less humane than those which guide the persons who desire to restrict their action, while of the value of any given experiment and the amount of suffering which it involves they are, owing to their special training, much better able to judge. When the men to whom the government has intrusted the care of its higher institutions of research shall show themselves incapable of administering them in the interest of science and humanity, then, and not till then, will it be necessary to invoke the authority of the national legislature.

THE OHIO STATE MEDICAL SOCIETY at its recent meeting in Columbus elected the following officers for the ensuing year:

President, Dr. F. C. Larimore, Mt. Vernon, O. Vice presidents: first, Dr. M. Stamm, Fremont, O.; second,

Dr. C. F. Clark, Columbus, O.; third, Dr. John S. Beck, Dayton, O.; fourth, Dr. Geo. W. Crile, Cleveland, O. Secretary, Dr. Thomas Hubbard, 205 Ontario street, Toledo, O. Assistant Secretary, Dr. H. M. W. Moore, Columbus, O. Treasurer, Dr. James A. Duncan, Toledo, O. Next place of meeting, Cleveland, O., third Wednesday in May, 1897.

The Brooklyn Department of Health has recently issued a circular showing that the laboratory for the production of serum is now able to provide serum that contains 200 units per cubic centimeter, or 2000 units per vial, which is just twice the strength of that heretofore issued. This new issue is known as Grade No. 1. Serum of a still higher grade, 2000–3000 units to the vial, will be issued in smaller quantities under a blue label, and is intended for use in severe cases only. The white label serum will be known as Grade No. 1, the blue as Grade No. 2. The average curative dose of diphtheria antitoxin is about 1000 units, but in severe cases or when the serum is not used until late in the disease, a larger dose, 1500 to 2000 units, is required.

The new serum will be furnished without charge to hospitals, dispensaries, and physicians if application therefor is made at the office of the Department of Health. In order that reliable statistics may be obtained, physicians who use the antitoxin issued by this Department are requested to fill out the form accompanying each vial and to forward the same to the chief of the laboratory. "Physicians who fail to make these returns will be unable to obtain further gratuitous supplies of antitoxin." This last quoted proviso has, in the judgment of the Commissioner of Health, been for the first time rendered necessary, upon any of his circulars of this nature, by the remissness of practitioners, who, having received the remedy free of cost, have not complied with a request for returns of results.

The following paragraph from the *Medical Press and Circular* for May 20th, refers to a subject interesting to all American surgeons, namely, a full and generous recognition of the great work of the great surgeon Lister. The author of the new biography of Lister is by Dr. Hermann Tillmanns of Leipzig, who, we believe, is at the present time one of the editors of the *Centralblatt für Chirurgie:* "Sir Joseph Lister, as already announced, is the President of the British Association this year, and, doubtless, partly in consequence of this, our contemporary, *Nature*, has published in its columns a sympathetic biographical account of the great surgeon, contributed by Professor H. Tillmanns. In addition, an excellent photogravure of Sir Joseph accompanies the paper. 'As long as there is an earthly immortality it must be his, for as long as ever surgery is scientifically discussed his name cannot fail to be mentioned.' Such are the closing words with which Professor Tillmanns feelingly shows his admiration for our countryman. Apart, however, from the interest which must naturally be felt in a description of Sir Joseph Lister's work, the sketch is worthy of note as emphasizing the praiseworthy way in which German surgeons from the first adopted his teaching."

By mistake it was stated in our issue of May 30th, that the British Association for the Advancement of Science would meet in Toronto, Can., this year. The year of meeting is 1897.

The department of the English government relating to factories has been officially investigating the frequency of lead-poisoning among the operatives in factories using the metal. It is not at all improbable that a bill will be introduced requiring that some more insoluble and inert salt be generally substituted for the dangerous "white-lead" of commerce.

CORRESPONDENCE.

AEROPOROTOMY.

To the Editor of The Medical News:

Dear Sir: I have before me a pamphlet entitled "Aeroporotomy," by Dr. S. W. Kelley. Dr. Kelley has expressed the wish that some of your readers might express an opinion upon the acceptability of the new word proposed in his paper. According to the author's explanation, the word should mean "to free, or to let air into the air passages," be it by means of tracheotomy or intubation. It is certainly pleasing for a philhellen to notice the tendency in our profession to use and to coin Greek terms. Unfortunately, however, when new terms are made, like the one mentioned, from the lexicon, by scholars who have learned to translate from the Greek, who, however, have never had the opportunity to understand and speak living Greek, such terms are seldom acceptable. I might furnish an endless number of amusing and also some rather painful incidents which happened in my own hearing when English, French, or German was spoken by people who had learned these languages in school and from books instead of in the natural way, by means of everyday intercourse with the people who speak these languages. It is easy enough to find a Greek word for a new idea, or a new invention, but if such a word cannot stand the test to which it is subjected by real Greeks, it becomes quite another question. Greeks love their language as they love their religion; they are jealous to preserve its purity. Except in everyday or vulgar language, they use no foreign word, and they extirpate incorrect elements, as soon as they have been recognized to exist, in newly-formed words and expressions, with the greatest severity and tact.

Dr. Kelley, in making the word aeroporotomy, has done exactly what other men of learning are in the habit of doing. I do by no means wish to criticise him personally, but I wish to call attention to the deplorable practice of introducing unscientific names into our lexicology. The word aeroporotomy is not acceptable. Ὁ ἀήρ, ἔρος, the air, Ὁ πόρος, passage, and ἀερόπορος means a journey through the air, as, for instance, in a balloon; ἡ τομή is a cut, an incision, an amputation, and cannot possibly be of service when we speak of either a journey through the air or of intubation. The respiratory organs are called ἀναπνευματικά ὄργανα. Many things are possible in regard to combination of Greek words, but I doubt whether a word could be found to express

all that Dr. Kelley wishes to express. At least, it would require quite some thought for a real Greek to tell whether or not such an acceptable word could be invented.

Dr. A. Rose.

332 East 15th Street,
New York.

A NEW URETHROSCOPE.

To the Editor of The Medical News:

Dear Sir: My attention has been called to a description in your last issue (May 23d) of a new (?) urethroscope, by Dr. J. A. Hawkins of Pittsburg. The resuscitation of discarded instruments as new inventions is by no means unknown, but a more flagrant case of this variety of plagiarism would be difficult to conceive, together with an evident ignorance of the modern urethroscope and the principles upon which it is constructed.

Dr. Hawkins commences his article with a short description of the Leiter instrument, in which he tells us that "as the line of vision is over the top of the mirror, little more than one-half of the light thrown in the direction of the mirror can be utilized, owing to the removal of a segment of the mirror to complete the axis of vision." Now, as a matter of fact, *there is no segment removed* from the mirror in the Leiter instrument, nor would there be any advantage in removing one, and as the mirror in that instrument renders the rays *parallel*, instead of "little more than one-half the light thrown in the direction of the mirror" being utilized *only a very small portion of the light*, corresponding exactly to the size of the urethroscopic tube used, is available,

That Dr. Hawkins was unable to use my "perfected" urethroscope to advantage, is not extraordinary, but any one at all versed in the physics of light will readily appreciate how that instrument must give a more powerful illumination than any form of concave mirror.

The instrument Dr. Hawkins presents is identical with *my* old skeleton modification of Leiter's urethroscope, retaining the Leiter handle and including *my* idea of using the Klotz tube, which, up to the time I so used it, never had a fixed light attachment. But Dr. Hawkins tells us that the *principle* of his (?) instrument is that of the ophthalmoscope, or in other words, that he makes a peek-hole through the center of the mirror, through which to observe the urethral field. It is unnecessary to explain here why he would obtain no greater illumination by this method, but it might be excusable to call attention to the fact that the first practical urethroscope ever made, that of Desormeaux, was constructed on this principle, as were all other reflecting urethroscopes, up to the time when Leiter overcame this objection. The first advantage Dr. Hawkins claims for his instrument is that it is lighter than the older instruments, though it weighs *two* ounces, when he certainly should be aware of the fact that my perfected urethroscope (which he could not adjust) weighs less than *one* ounce, constructed of the same material. His second claim that "all the light thrown in the direction of the mirror is utilized" simply shows that he knows nothing about it.

As I discarded the instrument Dr. Hawkins describes, some years ago for what the best urethroscopists in this country consider a better type, I feel unwilling to have it reappear upon the field without a vigorous protest.

W. K. Otis.

5 West 50th Street, New York,
May 26th, 1896.

SOCIETY PROCEEDINGS.

TWENTY-FIRST ANNUAL MEETING OF THE AMERICAN GYNECOLOGICAL SOCIETY, HELD IN NEW YORK, MAY 26, 27, AND 28, 1896.

Dr. William M. Polk, of New York, President.

First Day—May 26th.

Dr. William T. Lusk delivered the Address of Welcome. (See page 629.)

Dr. Paul F. Mundé of New York, presented a paper upon

VIRGINAL AND SENILE ENDOMETRITIS.

He said that chronic endometritis was a very common result of subinvolution, but so far as he knew, virginal endometritis had not been treated of in any text-book. In 1872, Leopold had reported in Leipzig a case of congenital erosion of the cervix, and last February, in Philadelphia, Dr. Charles B. Penrose had read a paper on "Congenital Erosions in a Split of the Cervix Uteri." Senile endometritis had received some attention, particularly by Dr. Skene. Dr. Mundé said that he had seen quite a number of instances in which a virgin uterus showed unquestionable signs of chronic and catarrhal inflammation, and where the lips of the os were so widely separated as to resemble the condition found in a well-marked puerperal laceration of the cervix. He did not believe that the profession was generally aware of the frequency of virginal endometritis, and of the symptoms produced by it. The sexual organs of the young girl ordinarily should not be subjected to local interference by the gynecologist, but there were limits to this rule. He had known young girls, twelve to fifteen years of age, suffer so much from a thick yellow discharge from the uterus as to make it justifiable to employ local treatment. In a case of a young girl suffering from severe menorrhagia, it had been found necessary to curette the uterus. The cervical canal was found to be quite patulous, and the curette removed fungoid granulations. The most common indications of the existence of endometritis were a more or less profuse muco-purulent discharge and menorrhagia. A correct diagnosis could only be made by both a digital and specular examination. The appearance of the cervix was that of a puerperal laceration of the second or third degree, so eroded and everted that a tenaculum could be used, as in a puerperal case, to bring together the lips. The treatment consisted in excising the hypertrophic mucous membrane, curetting the whole endometrium with a sharp instrument and, if there were considerable eversion, in bringing together the everted lips and suturing them. Amputation he did not consider necessary.

Regarding senile endometritis, the speaker said that for many years he had noticed that many women, after passing the change of life, suffered from a muco-serous, pungent discharge, which produced erosion of the lips of the cervix and a chronic bulbo-vaginitis. He had generally treated these cases on the basis of their being due to chronic endometritis. Many of the erosions could be healed by the application of a solution of nitrate of silver, half to one dram to the ounce. Women who had ceased menstruating for a year or two would seek advice because of a return of a sanguinolent discharge—merely a "spotting." This was, of course, a common indication of malignant disease, but not necessarily so. A positive diagnosis could only be made by careful microscopical examination. The foulness of the discharge and the gross appearances often seemingly pointed to malignant disease, and yet the microscope would show the condition to be only a chronic endometritis, with perhaps decomposition of the discharges from retention at the internal os. According to Skene, the presence of a fibroid in the uterus favored the development of senile endometritis, but this had not been his experience. In no case of this kind that had come under his observation had he felt that any severe operation, like vaginal hysterectomy, was justifiable.

Dr. Charles B. Penrose of Philadelphia said that in the case that he had reported there had been a split, five-eighths of an inch long, on one side of the cervix, without eversion, hypertrophy, or evidence of inflammation of the mucous membrane of the cervical canal. The condition seemed to be, in rare instances, congenital.

Dr. A. Lapthorn Smith of Montreal, said that he believed that dysmenorrhea and menorrhagia in young girls were often due to swelling and inflammation of the endometrium and the blocking-up of the canal, with consequent retention of the discharge within the uterus. Tight corsets, exposure of the feet to cold, and chronic constipation were the main factors in the causation of the condition. While the occurrence of sanguinolent discharge after the menopause might be due to senile endometritis, it was not safe to make such a diagnosis, unless confirmed by the microscope, because of the frequency of malignant disease in connection with this symptom.

Dr. Matthew D. Mann of Buffalo, said that in his address before the Society a year ago, he had called attention to the fact that both virginal and senile endometritis were often largely due to certain underlying constitutional states, notably, lithemia, which must be taken into consideration if one would be successful in their treatment.

Dr. Chauncy D. Palmer of Cincinnati, said that in certain cases presenting all the usual signs of virginity, he had observed enlarged and eroded cervices, with everted lips as after puerperal laceration. They had been relieved by trachelo-plastic operations.

Dr. Howard A. Kelly of Baltimore, said that it was difficult to be sure of virginity; the usually accepted signs of that condition could not be accepted as infallible. He had never seen endometritis in an undoubted virgin who had not been previously subjected to some local instrumentation. By the use of the knee-chest position and a small speculum, even a child could be examined and treated without injury to the hymen.

Dr. W. T. Lusk said that many young virgins suffered severely from backache, dysmenorrhea, and menorrhagia. Examination under chloroform would disclose an eroded and partially closed external os, with retained catarrhal secretion. A thorough dilatation of the os externum would relieve all the symptoms by allowing a free exit for the secretions, and would cause the uterus to return to its normal size.

Dr. J. Tabor Johnson of Washington, D. C., said that much unnecessary anguish was sometimes caused families by the medical attendant failing to appreciate the fact that there might exist these eroded clefts of the cervix without any suspicion of the patient's chastity. He would emphasize the point made in the paper regarding the absolute necessity of having the diagnosis of malignant disease of the uterus confirmed by microscopical examination. He had known of two uteri having been removed without this precaution having been taken, and subsequent microscopical examination showed that simple dilatation of the cervix and curetting should have sufficed to effect a cure.

Dr. Cyrus A. Kirkley of Toledo, O., read a paper on

LIABILITY TO PROSECUTION FOR DAMAGES IN ABDOMINAL SURGERY.

He said that in most instances the legal responsibility of the abdominal surgeon was not likely to be insignificant. The jury usually looked upon the medical expert as having a bias for the side calling him. There was a crying need for reformation in this matter of medical expert testimony. He commended the plan of having all the medical witnesses of both sides confer together before giving their testimony, and suggested that some of the present abuses might be avoided if the court were to appoint a medical commission to hear and determine the medical question involved in the case. The speaker also read a legal opinion upon the important question of the liability of a surgeon for opening the abdomen in a case in which death appeared to be certain if no such interference were done. The opinion stated that if well-qualified surgeons agreed that the operation was demanded under the circumstances, the operator should not be liable in damages, even though he had not been able to obtain the patient's consent.

Dr. Kelly recommended the following rules for the better protection of surgeons from prosecution: (1) Keep a written record of all cases and of the visits made; (2) carefully note, as far as possible, in the patient's language the symptoms and nature of the complaint and of the result of the first examination, record the proposed line of treatment and what is promised the patient; (4) never promise absolutely more than the mechanical result of the operation; (5) state clearly the risks of an abdominal operation, and (6) keep careful notes of the convalescence.

Dr. Edward P. Davis of Philadelphia said that an obstetrician might become defendant in a suit for malpractice in a case in which, after a normal parturition, a woman was suddenly seized two or three weeks afterward with pain, the result of the rupture of an ovarian tumor,

and died of sepsis. In the State of Pennsylvania, he said, that in suits for civil damages two physicians were selected to examine the plaintiff, one by the plaintiff and the other by the defendant.

DR. CHAUNCY D. PALMER of Cincinnati read a paper entitled

GYNECOLOGY AND GENERAL MEDICINE; THEIR RECIPROCAL RELATIONS.

He said that clinical experience furnished abundant proof of the intimate relationship between the pelvic organs and the whole nervous system. By the delicacy of her organization, woman becomes subject to a vast variety of disorders, particularly mental affections. Both menstruation and parturition, with their attendant exhaustion, diminish the woman's resistance to disease at such times, and render her particularly liable to infections. The speaker said that, while there was very little gynecology outside the domain of general medicine, there was scarcely a disease of the general system of much importance which did not affect the circulation, innervation, and functions of the pelvic organs. Almost every gynecological condition required some constitutional treatment, hence gynecologists should be physicians, as well as surgeons.

DR. JOHN BYRNE of Brooklyn, said he wished to personally thank the author for calling attention to this much neglected subject.

DR. FORD of Utica, said that there was danger that gynecology would fall into the hands of those who had been exclusively trained for this branch—a condition of affairs which would greatly favor the production of "fads." He cited a case in his practice illustrative of the good results to be obtained only by combining the forces of medicine and surgery.

DR. S. C. GORDON of Maine, said that he frequently resorted to the use of the curette in virgins, and that after such needed local treatment, the frequently associated anemia would be found to yield readily to appropriate constitutional treatment. He thought that there had been altogether too much sentiment shown regarding the examination and local treatment of virgins.

DR. ARTHUR W. JOHNSTONE of Cincinnati, presented the next paper on

THE CLINICAL IMPORTANCE OF THE MENSTRUAL WAVE. (SEE PAGE 636.)

DR. A. J. C. SKENE of Brooklyn, said that he had been much interested in Dr. Palmer's paper. He would define a specialist as one who knows everything about one subject, and a little about every other subject. Facts were at variance with the author of the paper, however, regarding women being peculiarly liable to disease because of the delicacy of their organization. Statistics showed that they were exempt from many diseases affecting males, particularly organic diseases of the nervous system. Regarding Dr. Johnstone's paper he would say that he thought Stephenson's ideas regarding the menstrual wave were worthy of the highest praise; they had proved in his experience a very valuable clinical guide. The paper was highly suggestive. For example, it was not long ago that many believed that epilepsy could be cured in women in cases in which there was palpable ovarian disease, by the removal of these organs; now, the neurologists express the opinion that true epilepsy has never been cured by any operation on any organ in the body.

DR. GEORGE J. ENGELMAN of Boston, said that at one time it had been believed that extirpation of the ovaries would cure many nervous disorders. His experience had been that the uterus had more control over such conditions than the ovaries.

DR. PALMER said that while thoroughly believing in the teachings of Stephenson, he could not accept Dr. Johnstone's statement that this menstrual wave had anything to do with the production of intermenstrual pain. Such pain, he believed, was due to ovulation occurring in an ovary, the cortex of which had become thickened or hardened.

DR. JOHNSTONE, in closing, said that as probably not more than five ovules ripened in the course of a year, he could not understand how intermenstrual pain could be ascribed to a thickening of the cortex of the ovary. He had never seen a case of intermenstrual pain relieved until the menopause had been brought on. He would ascribe such pain to stretching of nerve filaments, occurring on the anemic side of the menstrual wave.

DR. J. CLIFTON EDGAR of New York, presented a paper on

AIDS IN OBSTETRIC TEACHING.

In his introduction, Dr. Edgar stated his conviction that while the best method for a student to learn obstetrics is the personal care of parturient and puerperal women, still much of this experience will prove useless unless he has an intelligent appreciation of his work based upon a previous thorough training in the principles of the subject. It is this training of reason and perception and the aids to it, which have largely taken the place of the old theoretical lecture with which the author's attention is occupied. He is a firm believer in the advantage of models "possessing the third dimension of space" over elaborate description and illustration in the form of diagram. The rachitic pelvis, injuries to the pelvic floor, the relations of the uterus to surrounding parts are far better understood from casts and paper reproductions than from charts however well executed. The models are particularly useful in the training of nurses. A further advantage in their use is the fact that they may be kept obstetrically clean and may be used at the bedside or in the obstetrical clinic. While something has been done in this field, much remains, for example of uteri of known periods of gestation and of pelvic deformities which by their interchange may do not a little to raise the standard of obstetric teaching.

Models are not, in any sense, to replace bedside instruction—they are purely auxiliaries to instruction in its various forms and care must be exercised in their use. They undoubtedly lend a new interest to many points, otherwise obscure and dry. The natural size of the object should always be reproduced or a wrong impression may be conveyed. Diagrams, charts, and black-board illustrations are unsatisfactory and tiresome to the student

and can never be made to impart the practical knowledge obtainable with the aid of a few selected models.

The several varieties of aids to obstetric teaching are, for convenience, divided into five classes: (1) *Plaster Models.* (2) *Paper Reproductions of Clay and Plaster Models.* (3) *Composition Models.* (4) *Miscellaneous Models and Aids.* (5) *Electro-plated Plaster Models.* —For very small objects where minuteness of detail is required, *e.g.*, the non-pregnant uterus, electro-plated plaster models are recommended. A plaster cast is taken of the specimen, carefully dried and copper-plated.

The paper was most profusely illustrated throughout by half-tones of the specimens, models, and casts of all the varieties described.

DR. A. H. BUCKMASTER said that he had found paraffin especially useful as a material for making such models. It could be applied with a camel's-hair brush without causing the patient much discomfort, and from such a model, plaster casts could be taken.

DR. ROBERT A. MURRAY of New York, said that in this country physicians saw chiefly relative pelvic deformity. It should be noted that the average size of the child born at full term in Germany is 6½ pounds, whereas, in this country it weighs 7½ pounds.

DR. KING of Washington, D. C., suggested that in addition to the ingenious models and devices already in use by Dr. Edgar, that he should furnish to the student some form of apparatus which could be taken by the latter to his home and studied at his leisure. It would also be desirable to have made for use in demonstrations before large classes a model of the pelvis several times larger than the normal.

DR. EDWARD P. REYNOLDS of Boston, agreed with the reader of the paper that it was impossible to properly teach obstetrics by models not having the three dimensions. It was particularly desirable that the student should be provided with models which would present to him in a graphic manner the mechanism of labor.

DR. EDWARD P. DAVIS also complimented Dr. Edgar on the ingenuity and originality displayed in these models, particularly those illustrating the lacerations of the parturient tract, and the methods by which they should be repaired. When improved methods would admit of taking skiagraphs through the human body with the X-rays and an exceedingly short exposure, we would probably have another important addition to the means at our disposal for instruction.

DR. EDGAR said that he had not had much success with paraffin.

DR. S. C. GORDON of Portland, Me., presented reports of

TWO CASES OF PREGNANCY FOLLOWING REMOVAL OF BOTH TUBES AND OVARIES, WITH REPORTS OF SOME OTHER INTERESTING CASES.

The first case was that of a woman, thirty-six years of age, from whom both ovaries and tubes had been removed in May, 1891. She became pregnant in June, 1894, and was confined in February, 1895. Since then menstruation had been regular.

The second case was that of a woman of thirty-three years from whom, in 1894, he had removed both ovaries and tubes, but who had continued to menstruate regularly after the operation. Last March she was delivered of a healthy child. Of course, some ovarian tissue must have been left, but the question was as to how the ovum reached the cavity of the uterus.

The next case reported was one of tubal pregnancy, afterwards becoming abdominal. At the time of operation a tumor was found lying in the general cavity, and from it was removed a fetus of about five months, which gasped a few times.

The next case was that of a woman thirty-five years of age upon whom he had operated for a tubal gestation. The tube contained a fetus of about six week's development, and the hemorrhage was all within the peritoneal coat.

EFFECT OF COMPLETE HYSTERECTOMY UPON THE VAGINA.

DR. GORDON then took up the question of the effect of complete hysterectomy on the length of the vagina. By his technic, the broad ligaments were drawn up as soon as they had been cut, and after the completion of the operation the vagina was lifted up above the normal position, so that the vagina was actually lengthened to the extent that it had been drawn up by the suture. He had only found shortening of the vagina in cases in which the cervix had been left.

DR. R. STANSBURY SUTTON of Pittsburg reported

CASE OF DOUBLE OVARIOTOMY, FOLLOWED BY PREGNANCY AND DELIVERY AT TERM.

He said that in October, 1892, Mrs. P. had been admitted to the hospital in a very feeble condition. He had made a diagnosis of ovarian cystomata, and had given an unfavorable prognosis. She had had only one child, six years before. He had removed by operation two multilocular ovarian cysts, searing the pedicle on one side with the Paquelin cautery, but omitting this on the other side, as the cautery failed to come up to the proper heat when wanted. The stump of this second pedicle lay close to one horn of the uterus. The uterus was a little larger than normal, and as it was retroverted, he had raised it and fixed it in the lower angle of the abdominal wound. On June 10, 1894, she gave birth to a large child, and this year was delivered of still another child.

DR. A. LAPTHORN SMITH reported the case of a woman twenty-eight years of age, the mother of two children. Abdominal section had been performed upon her just after a menstrual period, and both ovaries and tubes extirpated. One month later the breasts gave indications of pregnancy, and in due time she was delivered of a child. She had apparently conceived immediately after menstruation, and the fecundated ovum had passed into the uterus just before the operation.

DR. ERNEST CUSHING referred to a case of abdominal pregnancy that he had seen in which the fetus lay in the abdomen, and the placenta partly within, and partly without the tube. He felt convinced that there should be no shortening of the vagina, whether the cervix were removed or not, though personally he preferred to do the complete operation.

DR. A. PALMER DUDLEY of New York, said that he had been deeply interested in conservative surgery on the appendages, for several years past, and he could now point to the records of six cases in which pregnancy had followed such work. Three of these women had already been delivered of living children, and three were now pregnant. One reason for his success he attributed to the use of the catgut ligature, which would soften sufficiently early to allow the tube to become patent.

DR. ARTHUR JOHNSTONE said that the leaving behind of a small piece of ovary did not necessarily preserve the menstrual function. The cases reported might be explained by the existence of "the third ovary," and by the presence of more than one opening to the tube—a not uncommon condition.

DR. GORDON cited a case in which menstruation had persisted not only after a double ovariotomy, but even after the subsequent removal of all the uterus except the cervix.

DR. SUTTON said that if the ligature were applied sufficiently close to the horn of the uterus to cut off the sympathetic nerve, he did not believe there would be any further menstruation.

(To be continued.)

AMERICAN PEDIATRIC SOCIETY.

Eighth Annual Meeting, held at Montreal, Canada, May 25, 26, and 27, 1896.

JOSEPH O'DWYER, M. D., President.

Owing to the necessary absence of the President, DR. JAMES C. WILSON, the first vice-president presided. The first session was opened by the reading of the President's Address, entitled

THE EVOLUTION OF INTUBATION.

This was prepared at the request of the Council, and was a paper of the greatest interest, as it described the labors which Dr. O'Dwyer pursued with untiring devotion to a great idea through five long years. A bivalve tube was first used, but after three years of continuous effort it was abandoned, and experiments were begun with the solid tube. The paper described the various experiments made with various alternating failure and success, until at last obstacle after obstacle was overcome and imperfection after imperfection was removed. As a result of this patient toil, perfected instruments were given to the profession, a very rare thing in the history of medicine. The various steps taken in attaining this great result were narrated with the simplicity and modesty which have always characterized the literary work of Dr. O'Dwyer. A complete set of instruments, showing the evolution of intubation from the first bivalve tube to the present perfected model, proved of the utmost interest.

The first paper was read by DR. GEORGE N. ACKER of Washington, D. C., on

GANGRENE OF THE LUNG, FOLLOWING TYPHOID FEVER.

DR. J. H. FRUITNIGHT of New York, read a paper on

MALIGNANT ENDOCARDITIS,

and presented a specimen. As the bacteriological examination showed that the condition was due to the presence of streptococci, the author advocated the use of streptococcus antitoxin serum in such cases.

At the second session, DR. A. H. WENTWORTH of Boston, read an exhaustive paper on

LUMBAR PUNCTURE,

and reported twenty-nine cases. He affirmed that, while normal cerebrospinal fluid contains neither fibrin nor cells and is clear, it is always cloudy in cases of meningitis, though the cloudiness is sometimes very slight. This is caused by cells, the character of the cells differing with the variety of meningitis. The operation, the author believes, offers a valuable means of diagnosis. For such purposes, however, the microscope is essential, and inoculation experiments are also of value. This was followed by a paper on

TAPPING THE VERTEBRAL CANAL, WITH REMARKS ON LOCAL TREATMENT OF MENINGITIS,

by DR. AUGUSTUS CAILLÉ of New York. He reported twenty-one cases, and believed that a study of the cases reported up to the present time would certainly convince the most skeptical that Quincke's puncture is of positive value as a method of diagnosis. It is simple and usually easy of performance.

In two cases Dr. Caillé injected antiseptics into the subarachnoid space, but without material results. He proposes in some future case to lay bare the dura by removing a button of bone and irrigating from a lumbar puncture upward through an opening in the dura.

DR. C. D. JENNINGS of Detroit, also read a valuable paper on

LUMBAR PUNCTURE,

and reported practical experience.

DR. FLOYD M. CRANDALL of New York, read a paper on the

OCCURRENCE OF INFLUENZA IN CHILDREN,

and reported local epidemics.

DR. SAMUEL S. ADAMS of Washington, D. C., reported an extremely interesting case of

TEMPORARY INSANITY, FOLLOWING TYPHOID FEVER.

DR. FREDERICK A. PACKARD of Philadelphia, reported a case of

ENDOTHELIOMA OF THE BRAIN, WITH ATROPHY OF THE PARALYZED MEMBERS.

DR. HENRY JACKSON of Boston, read a paper on

NASAL FEEDING IN DIPHTHERIA,

in which he advocated feeding by means of a soft tube passed through the nose into the esophagus, in certain cases of diphtheria. As this can be done with ease, it does much by preventing exhaustion of the child's strength.

DR. WILLIAM OSLER of Baltimore, read a paper on the

CLASSIFICATION OF TICS, OR HABIT MOVEMENTS.

He made the following classification: (1) Simple tic or habit spasm. (2) Tics with superadded psychical phenomena; maladie de la tic convulsif; or Gilles de la Tour-

ette's disease. (3) Complex coördinate tics. (4) Tic physique. An imperative idea is the psychical equivalent of, and has an origin similar to, the motor tic. Each of these subdivisions was elaborated and illustrated by practical examples.

The third session was devoted to the

ANTITOXIN TREATMENT OF DIPHTHERIA.

The report of the Collective Investigation Committee of the Society upon the results of the

ANTITOXIN TREATMENT IN PRIVATE PRACTICE

was read. Over five thousand cases were reported, the results being, on the whole, more favorable than any extended reports that have thus far appeared. A complete report will soon be published in full. Dr. P. A. Packard reported favorable results of the antitoxin treatment, and Dr. S. S. Adams read a paper on the

COMPARATIVE RESULTS OF THE TREATMENT OF DIPHTHERIA, WITH AND WITHOUT ANTITOXIN, IN THE DISTRICT OF COLUMBIA.

It appears that the death rate from diphtheria in the District of Columbia, since the appearance of antitoxin, has materially diminished. Dr. A. Seibert of New York, read a paper on

SUDDEN DEATH AFTER ANTITOXIN INJECTIONS.

He reported a series of striking experiments which showed that the injection into animals of carbolic acid, even in very weak solution, was constantly followed by most characteristic spasmodic movements. Another series of experiments was made to determine the effects of subcutaneous injections of air. The results seem to show that antitoxin can contain but infinitesimal quantities of carbolic acid. They also render the proposition reasonable that the few sudden deaths reported after the injection of antitoxin might be due to the injection at the same time of air. The general discussion elicited by these papers was extremely interesting and showed a unanimous and very strong sentiment in favor of antitoxin.

At the fourth session, Dr. Rowland G. Freeman of New York, read a paper on

LOW TEMPERATURE PASTEURIZATION OF MILK.

He proved that 67° C. was sufficient to kill numerous pathogenic bacteria and various atmospheric bacteria, and referred to the importance of avoiding unnecessary heat in the preparation of milk for infant's use. He presented a new apparatus of simple construction, designed to Pasteurize milk at 67° C.

Dr. Charles W. Townsend of Boston, reported several cases of

THIGH-FRICTION IN INFANTS.

Dr. William P. Northrup of New York, reported a most interesting case of

APPARENTLY RELAPSING CEREBROSPINAL MENINGITIS,

followed by death and autopsy, which elicited a warm discussion on the pathology and diagnosis of meningitis.

Dr. Henry Lafleur of Montreal, reported a case of

INSOLATION IN AN INFANT OF THIRTEEN MONTHS.

Dr. A. D. Blackader of Montreal, reported a case of

ENLARGEMENT OF THE LIVER

in a young child, with symptoms closely resembling typhoid fever.

Papers were read by title, by Drs. B. K. Ratchford of Cincinnati, F. Forchheimer of Cincinnati, Irving M. Snow of Buffalo, and Henry D. Chapin of New York.

The last session was devoted to the presentation of pathological specimens. Specimens being presented by Drs. Rotch, Holt, Caillé, Adams, Packard, Acker, Freeman, and Townsend.

The following officers were elected for the coming year: President, Dr. Samuel S. Adams, Washington; first vice-president, Dr. W. S. Christopher, Chicago; second vice-president, Dr. Charles W. Putnam, Boston; secretary, Dr. Frederick A. Packard, Philadelphia; treasurer, Dr. Charles W. Townsend, Boston; recorder and editor, Dr. Floyd M. Crandall, New York; member of council, Dr. William Osler, Baltimore; chairman of council, Dr. William P. Northrup, New York.

REVIEW.

Morphology of the Cerebral Convolutions, With Special Reference to the Order of Primates. By Andrew J. Parker, M.D., published by the Philadelphia Academy of Natural Sciences, 1896.

In the prefatory note by the editor, Dr. F. X. Dercum, we are told that this remarkable, and for this country, really original publication, which was awarded the Boylston prize in 1890, is published at his suggestion on the advice of the publication committee, by the Academy of Natural Sciences.

It is impossible in a brief notice to give any adequate idea of the tireless energy, scientific zeal, accurate observation, and logical interpretation which this book of 100 octavo pages and 35 beautifully executed plates, some of them in colors represent the very nature of the work, places it beyond the requirements of the general practitioner, but it should find a place in every public library, in every laboratory reference library, and on the bookshelves of every scientist interested in the problems of neurology and comparative anatomy. The work is an imperishable monument to the memory of its talented author.

CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MAY 16, 1896.

May 9th.—Medical Inspector R. A. Marmion detached from the "Newark," ordered home, and placed on waiting orders.

Surgeon L. B. Baldwin detached from the "Cincinnati" and ordered to the "Newark."

Surgeon N. H. Drake detached from the "Franklin" and ordered to the "Cincinnati."

Passed Assistant Surgeon I. W. Kite detached from the Naval Hospital at New York and ordered to the "Franklin."

Passed Assistant Surgeon P. Leach detached from the Naval Laboratory, New York, and ordered to the Naval Hospital, New York.

THE MEDICAL NEWS.
A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXVIII. NEW YORK, SATURDAY, JUNE 13, 1896. NO. 24.

ORIGINAL ARTICLES.

MULTIPLE CALCULI OF THE PROSTATE.[1]

BY L. BOLTON BANGS, M.D.,
OF NEW YORK;
CONSULTING SURGEON TO ST. LUKE'S, THE CITY, AND THE M. E. HOSPITALS; AND ATTENDING GENITO-URINARY SURGEON TO ST. MARK'S HOSPITAL.

BY calculi of the prostate, is meant calculi which form within the body of this gland from material furnished by it exclusively; which have not come from the urinary tract, and primarily have no admixture of urinary salts. They form insidiously, grow slowly, and occupy a sac which they painlessly make for themselves within the tissue of the prostate. They are usually multiple, but under certain conditions one or more may amalgamate, forming a single stone, which may attain a considerable size. They are usually found during mid-life, but they have been said to exist even in childhood. Ashurst quotes a case of Dr. Barker of Bedford, England, who removed a stone from the prostate of a man aged twenty-nine years, who had suffered from incontinence of urine from his fourth year. This mass consisted of twenty-nine pieces, hard and white, closely soldered together, and measuring nearly five inches in length. If this mass of calcareous material began at the early age mentioned, it must have been originally very small for, as is well known, the prostate at four years of age measures but a few (12 to 13) millimeters in diameter. Erichsen mentions a lad of nineteen, from whose prostate he extracted two calculi. In view of the theory of the production of prostatic calculi, to which reference will be made, I should be inclined to refer these cases to a urinary derivation and that they had made a sac for themselves in the prostates of these boys as the latter developed.

Under the head of "prostatic calculi," the text-books record many interesting cases, but some of these are not such, strictly speaking, and should be described as urethral calculi, for they have formed upon a nucleus lodged in the prostatic portion of the urethra, and have grown from the accession of *urinary* salts. Some of these attain great size, and have been known to be perforated by a channel for the escape of urine. I have removed several, of small or moderate size, from the prostatic sinus, or from the membranous urethra behind a stricture, or which had formed upon fragments lodged in the prostatic urethra. But these were all composed, either of uric acid, or oxalate of lime, or the ammonio-magnesium phosphates, or of a mixture of these salts, and bore no relation to the calculi which we are now considering.

The number of calculi which may be contained in a sac in the prostate seems to be almost unlimited. Mr. Henry Morris speaks of having removed on several occasions between two and three hundred from the same prostate. Dr. Keyes, some years ago, reported an equally large number, and there are many cases on record in which thirty or forty were found in the substance of the prostate, the tissues being "literally studded with them." As a rule, they do not cause symptoms excepting when erosion into the bladder or urethra has taken place, or when the mass has attained considerable size. Hence they may be easily overlooked during the life of the individual. On the autopsy table they are not infrequently met with, and sometimes their number or size is such as to occupy almost the entire interior of the organ without having given rise to any marked symptom during life. The latter has occurred in my personal experience, and I have also observed cases where the gland was not only sacculated within but was apparently circumferentially enlarged. Hence, in these days of castration for enlarged prostate, the possibility of such an error in diagnosis should not be forgotten. On the other hand, there are cases in whom irritability or pain about the neck of the bladder can only be explained by the presence of these calculi. In some there may be a sense of weight and pain in the perineum and many of the local symptoms of enlarged, inflamed, or irritated prostate. Of course, I admit that the diagnosis of intra-prostatic calculi may be exceedingly difficult, unless some of the conditions to which I have already referred are present, namely: the surface of one of the calculi being felt in the prostatic urethra, or their having attained a great size, or the sensation of "crackling" being elicited by rectal palpation. According to my observation, the sensation of "crackling," on palpation through the

[1] Read before the Surgical Section of the New York Academy of Medicine, May 11, 1896.

rectum, or palpation combined with the introduction of an instrument, as mentioned by many authors, may be absent, and yet the prostate may be full of calculi.

The theory of the production of these calculi seems to be that they start from the minute concretions which are found microscopically in a large proportion of prostates examined after death. Sir Henry Thompson gives a very interesting account of these concretions, and other observers regard them as a *normal* product of the tubules of the gland. But considering the function of the prostate to be the secretion of a bland, though acid fluid for admixture with the semen, I should regard them as abnormal, and the result of some disturbance of function. Later on, their presence in the tubules increases the irritation of the latter, and the concretions gradually receive accessions in size by a deposition of earthy material; the intervening structure of the prostate breaks down, or is absorbed, and a sacculation or pouch is formed in which the calculi lie. Originally, they are of a rounded form, but by compression and no doubt by a certain amount of friction with each other, they lose their spherical shape and become faceted, as seen in the specimen now shown you. They are usually found to be composed of phosphate of lime, a very small proportion of carbonate of lime, and perhaps some animal constituents. These constituents vary in their relative proportions, according to the size of the calculus, the smaller the stone the larger the proportion of animal matter. They are not to be confounded with urinary calculi, although it is true that in some cases where the stone projects from below upward into the urethra, or where a communication with the latter or with the bladder has formed a certain amount of urinary infiltration may take place, and especially if there be prostatic hypertrophy, or any other cause which produces ammoniacal decomposition of the urine, the latter may deposit upon the surface of the calculi a layer of triple phosphates. In the specimen you will observe there is no adventitious deposit.

In illustration of some of the foregoing facts, I beg leave to present the following typical case, which may also be interesting because of questions of diagnosis:

The patient referred to me by Dr. N. G. MacMaster of this city is a man sixty-five years of age, whose general health has always been good. He had gonorrhea when he was eighteen years of age, and again two years later, since which time he has been free from infection. At twenty-five years of age he had a stricture of the anterior urethra operated on, and for two months after the operation sounds were passed. Since then he has had no instrumentation for this condition. About five years ago he passed by way of the urethra a small calculus, and subsequently at different times up to August, 1894, the same thing occurred. Since then there is no history of any calculus. These were probably of renal origin, for the symptoms accompanying the passage of these calculi were always the same, namely, a dull, bearing-down sensation in the left kidney, which he describes accurately, and frequency of urination; but there was no acute pain, no nausea and vomiting, and no prostration. Shortly before coming under observation, he had suffered from frequent nocturnal urination and from some difficulty in starting his stream, which would splutter and dribble, but these symptoms had been relieved by the repeated introduction of a sound by his family physician. During one of these treatments his doctor had appreciated a grating sensation in the deep urethra. At present his chief complaint is of an uncomfortable feeling in his deep urethra—an irritation or sensation of itching. He also has a fixed idea that if he is not attended to his stream will diminish in size. He urinates during the day once in three or four hours, and without pain or difficulty.

On examining him, a calculus was found lodged in the prostatic urethra, but its size and character could not be determined, and all attempts made to seize or dislodge it were ineffectual. At the time, believing it to be one of the renal calculi which had become fixed, his family physician received some suggestions which I had found useful in dislodging the stone in other cases. These were used without success. As the patient did not suffer very much, and business requirements calling him to a distant part of the country, he postponed operation and went along comfortably for nearly a year. In October, 1895, he reappeared in about the same condition, but his symptoms were somewhat intensified. The stone was easily felt and all efforts to dislodge it proving futile, I sent him in to St. Mark's Hospital and, under ether, opened his perineum. A stricture of the urethra at the bulbo-membranous junction was found and was incised. With the exploring finger, a stone was felt projecting from the body of the prostate into the urethra in the median line. It was deeply imbedded, only its upper surface being level with the surrounding tissue. When this was removed another calculus was felt obstructing (slightly) an opening which led into a pouch occupying completely the body of both lobes of the prostate. In this pouch were found twenty-nine calculi, closely packed together and faceted. These were removed, not without some difficulty, because of the small size of some of them and their number. There was no pus or urinary infiltration in this cavity or sac, which was distinctly felt to close or contract upon itself, and at the end of the operation it was possibly about one-third of its original size.

The patient made an uneventful recovery, and

in eleven days was sitting up without having had a bad symptom.

The laboratory report was that the stones consisted of calcium phosphate.

You will observe that these calculi gave rise to no symptoms until they began to emerge into the prostatic urethra, not at any time did my patient have any serious distress. His chief complaint was only an undefined uncomfortable feeling in his deep urethra, and an irritation or sense of itching in the same region. A question in diagnosis was suggested to me by the conditions found at the time of operation. Up to the time of the latter, I had rather taken it for granted that the calculus, detected by the grating of the sound, was one which had come from the kidney and had become permanently lodged in the prostatic urethra. This fixation being accounted for by an apparent moderate enlargement of the prostate, which examinations by the rectum showed. Of course this enlargement disappeared when the sac contracted after being emptied. On finding this sac, the question naturally arose: Were the calculi which he passed in 1890, and subsequently, of renal origin; or, were they of prostatic origin expelled into the urethra?

It is true that the symptoms pointing to their renal origin were mild, and might be suggestive of doubt, nevertheless he *did* have renal symptoms referred to one kidney, and relief followed so soon upon the passage of the calculus that their relation of cause and effect is a reasonable deduction. Notwithstanding the *mildness* of these symptoms, which, by the way, is quite in the line of experience, I am inclined to the opinion that his first calculi were of renal origin, and that subsequently sufficient lesion of the prostatic urethra took place to permit the detection of primary prostatic calculi. As to the source of the latter, there can be no doubt. Taking the clinical history and their chemical composition into consideration, it is evident that these stones formed primarily in the prostate, and had no relation whatever to those formed in the kidney.

MEMBRANOUS ANGINA, SIMULATING DIPHTHERIA, WITH OBSERVATIONS ON ETIOLOGY.

By S. W. S. TOMS, Ph.G., M.D.,
BELLPORT, L. I., N. Y.;
FELLOW OF NEW YORK ACADEMY OF MEDICINE.

THE cases here reported are not those accompanying the acute exanthemata, but those usually designated by the laity as "ulcerated sore throat," "membranous sore throat," "diphtheritic sore throat," and the like—synonyms that have been handed down through the medium of our older medical men, and to which is attached the same idea that is mentally associated by them with "scarlatina" when speaking of a *mild* case.

These cases have been of peculiar interest to me in studying the contributing etiological factors and conditions that seem to underlie each individual case, and are regarded of importance because of the lack of literature on the subject, or the ambiguity of that which is available. In works of authority[1] at my command I do not find such treated of as a disease *per se.* In some, a few cursory lines are devoted to the subject, while many entirely omit all mention of such a condition.

CASE I.—During June, 1895, I attended a girl six years of age, who had a follicular tonsilitis, slight pyrexia, dysphagia, and enlargement of the tonsils. The child was disinclined to exertion, and this condition existed for a day or two before the sore throat appeared. The bowels were constipated, but had been moved by a domestic laxative before I was called. Under appropriate antiseptic gargles, the local condition disappeared within a few days. I requested to see the child use the gargle, and at once saw that she protruded the lower jaw in such a manner as to raise the base of the tongue, preventing the gargle coming in contact with the tonsils. After this was overcome, a marked improvement followed in a few hours. Sanitary surroundings good.

CASE II.—On July 3d, I was called to see a boy, aged eight, of good physique. His general condition appeared good; there was no acceleration of the pulse or increase of temperature. I was told he had been feverish and restless for two nights before. The boy was unable to articulate, had dyspnea, nasal obstruction, and dysphagia. The entire fauces and part of the hard, and entire soft, palates were covered by a thick, tenacious membrane of a dirty grayish color, without any perceptible odor of putrescence; bowels constipated for several days. As the boy had a low order of intelligence (an hereditary feature), I prescribed a mixture of tr. ferri chlor. and glycerin, to be used with a swab several times a day, instead of relying on the problematical results from attempts at gargling on his part, or the still more doubtful use of the spray in the hands of his mother. Three days afterward, I heard he was "just the same," but a week later that he was well. Although the appearance of the local lesion alone would have carried conviction that the trouble was diphtheritic, yet there was absent those cardinal concomitant manifestations which convey to the mind of an observant practitioner, reasonable evidences of that disease. The toxemia as shown in physical and mental depression, muscular weak-

[1] Pepper's "System of Medicine"; "American Text-book of Medicine," Pepper; Hare's "System of Therapeutics"; "Cyclopedia of Diseases of Children," Keating; Osler's "Practice of Medicine"; Strumpell's "Text-book of Medicine."

ness and hebetude, elevation of pulse-rate and general pyrexia, and also the peculiar fetor to the breath, were all absent. The house was situated in close proximity to outhouses, all of which were kept in a most unsanitary state; the stench from them was sickening, especially at night. No other case occurred in this family.

Case III.—On July 11th, I attended A. P., aged thirty, a married woman, in her third month of gestation, well nourished and of large physique, whose general health had been disordered for some months. Temperature, 102.5°, pulse 90; she suffered severely with pain in the left tonsil, which was acutely swollen and congested, and had considerable tumefaction in the cellular tissue of the neck externally. She stated she had had chilly sensations in the previous afternoon, but apart from that had retired apparently in her usual condition of health. In the morning, a white patch appeared on the tonsil, which spread rapidly, despite the energetic use of antiseptic local treatment, to the surrounding structures, and by the following day covered the pharynx, soft palate, uvula, and partly the opposite aspect of the throat, although it did not involve the other tonsil. The fever ranged throughout about 99° to 100° F., and the pulse from 85 to 100, of good and regular quality and fair tension. The urine was examined for albumin several times during the illness, but none was ever present. It was ten days before she was able to leave her bed, and during this time she suffered at times very severely from the pain, dysphagia, and insomnia. There was considerable nervous excitement at times, and on one occasion mild delirium for a few hours. There was a manifest hysterical element, but at no time was there clinical evidence of toxemia, as hebetude, prostration, or threatening symptoms of abortion. The cervical glands were enlarged, and inflammation involved the Eustachian tube and middle ear, causing intense earache, yet none of the parts involved suppurated. The pseudo-membrane was tenacious, white, and thin. There was no ulceration nor fetor. When forcibly removed, it left a raw, bleeding surface, and reformed in an hour or so, extending beyond the former limits. The mouth could scarcely be opened, and the patient at times could not talk, and it was with the greatest difficulty the sprays and local treatment could be carried out or nourishment taken. Within a few hours, on the sixth day, the entire membrane desquamated in large pieces, leaving the fauces entirely denuded of mucous membrane. The patient found it so painful that even nourishment could not be taken, because of the irritation produced. A vegetable astringent gargle, containing carbolic acid, was the only thing that gave even temporary relief until new membrane began to form, which was fully completed within three days. Paralysis of the soft palate followed, yielding within a week under $\frac{1}{80}$ grain doses of strychnia, three times a day. The treatment composed of a gargle of sodii hyposulphite, ac. sulphurus, tr. cinchona, glycerin, and water, with sprays of H_2O_2 diluted, and application once daily of twenty grains to the fluid ounce of ac. salicylic disolved in alcohol, with a brush probang to the pseudo-membrane, that removed it most efficiently. An iron, quinin, and strychnin tonic, containing small doses of bichlorid of mercury, was given throughout the course of the disease. The case was in charge of a trained nurse, who observed all necessary safeguards as if it were one of true diphtheria. Ice and oleate of mercury to the neck gave much relief.

Case IV.—On August 1st, F. K. P., aged thirty-two, the husband of the preceding case, a plumber by occupation, developed a sore throat the day following the cleaning out of a foul cesspool. The onset was not so sudden as in the preceding case, but followed a slight rigor, with considerable febrile movement and a pulse of 100. General malaise, backache, and muscle pains in the lower extremities. On examination of the throat, a small, brownish-gray patch existed posterior to the right tonsil, between it and the posterior pillar. There was no swelling in the pharynx or neck, and only a slight circumscribed hyperemia was noticeable in immediate connection with the patch. This was cauterized with the salicylic acid solution, followed by sprays and gargles, together with constitutional treatment; yet it rapidly spread over the entire fauces and hard palate, almost covering the vault of the mouth. In this case there was no tonsilitis, cervical glandular involvement, earache, nor cellulitis of the neck. The pain was quite intense for two or three days, swallowing was difficult, and there was considerable muscular weakness, yet no profound prostration or other evidences of toxemia. While applying the local application to the membrane, the patient coughed violently into my face, carrying considerable of the *debris* into both of my eyes. I had to go down a flight of stairs, through two rooms, into the kitchen, to the pump, before I could wash the particles from my eyes, yet I had no trouble following the exposure. The membrane was dirty gray in color, without fetor, and entire desquamation took place on the fifth day. No difficulty was experienced in opening the mouth at any time. Paralysis of the soft palate persisted for over a month, with changed voice.

Although there is an apparent causal relation between these cases, being husband and wife, yet the fact remains that the wife had recovered some time before her husband developed his trouble, although he had been more exposed to it during her sickness than in her convalescence. It is significant that this developed the day following exposure for some hours to sewer-gas, together with the fact that his wife doubtless contracted hers from a similar source, and gives weight to the belief that a common agent was directly respon-

sible for the infection of both. I found that the wife washed her dishes in a kitchen sink, which had no trap, over which she stood three times a day for some time, and this was directly connected with the cesspool, some twenty feet from the house.

These people vacated the house after the wife was convalescent. It was subsequently occupied by another family with three small children. The mother and one child had membranous sore throats. The plumbing was overhauled, when the trouble at once subsided. A son, of about twelve years, while helping his father clean a cesspool in a different part of the village, standing over the opening, was affected two months afterward in the same way as the cases above described.[1]

CASE V.—On the same date as Case III, another occurred in a young man, aged twenty, by occupation a baker, whose duties required him to get up after midnight and work until early in the morning in a cellar where damp air and furnace heat commingled. Here he worked, half dressed, while the night air entered in draughts through open windows flush with the damp ground outside. Two nights previous, he had slept out of doors on the beach by the ocean, exposed to the chill air. When I saw him in bed, his neck was considerably swollen on both sides; his temperature was about 100° F., and the pulse 100, where it remained throughout, being irregular and always very compressible. There was very little pain or discomfort in the throat, and patient gargled and took nourishment freely most of the time. Upon examination, the throat presented enlarged and inflamed tonsils, both of which, together with the fauces and post-nasal spaces, uvula, and entire soft, and part of the hard palate, were covered with a thick, tenacious, grayish-white membrane which left raw, bleeding surfaces when removed, and quickly reformed, nor did it disintegrate. Considerable ulceration took place, although it was devoid of fetor at all times. The uvula became necrotic, and sloughed off about midway. There were some evidences of constitutional disturbance in this case, and two or three times he became faint when placed in an upright posture. The boy was very anemic before his illness, and this was very marked during his convalescence. A large eczematous patch of superficial ulceration on the left temporal aspect of his head complicated his sickness, and was curetted down to healthy tissue, and cauterized with pure carbolic acid. The entire desquamation of the membrane took place on the sixth day. Paralysis of the soft palate followed, with nasal voice, lasting for over a month. On the eleventh day of his illness, the patient left for home, a distance of about thirteen miles, without my knowledge or consent. He was very weak and debilitated, and I learned he was quite ill for several days afterward. I incidentally heard that he had quite extensive muscular incoördination in both lower and upper extremities; to what extent, and how long it persisted, I was unable to ascertain, but he subsequently recovered from these. There was no albumin found in the urine at any time.

The sanitary surroundings of the buildings and outhouses where this patient resided were as bad as could be imagined. This patient could not have contracted it from any other case, nor was it possible others developed from him. The two worst cases developed on the same date in different localities, and in both ample opportunity existed for others in the houses to contract it, especially in this last case, where a number of young children lived, and some had been many times exposed directly in the room, and by clothing and other fomites, yet none contracted it.

CASE VI occurred in a weakly boy, aged ten, on 29th of July. It pursued a typical course of chilly sensations, followed by sore throat, anorexia, accompanied by constipation, membrane desquamating on the fifth day. This case was apyretic, except for the first twenty-four hours.

CASES VII and VIII.—Two other children in same family developed sore throats while the last case was convalescing—about the tenth day. They had a very mild attack, so much so that I did not make any personal visits, simply directing the treatment through the mother, who made two reports at my office.

With this family also existed the foul outhouses, pig-pens, hen-coops, and a back yard, where all the slops from the kitchen were thrown, just outside the door.

That these cases are unique, I think, will be readily admitted, from the remarkable uniformity in their clinical course and in the duration of local manifestations. Since microscopical revelations have apparently shown such variation in symptoms of diphtheria in different subjects, yet mortality statistics are tolerably uniform, taking, say, one thousand cases in which the Loeffler bacillus is demonstated to be present. The following is a fair concensus of opinion: "All observers have found the mortality higher in those cases in which the diphtheria bacilli were present than in those in which they were absent. In true diphtheria, the mortality has been found to vary from twenty-five per cent. to seventy per cent., while in pseudo-diphtheria it varies from nothing to twenty per cent."[1]

[1] The habitat of the microbe, when outside of the body, is not known, but it is believed to live in surface soil which is contaminated with organic matter. It is known to grow in excretory refuse.—Pepper's Text-book, p. 377.

[1] Scientific Bulletin No. 1, Health Department City of New York, from Bacteriological Laboratory.

The brilliant achievements of bacteriology, made possible by the microscope, have placed it within the power of health boards and scientific bodies to supply safe and satisfactory means of limiting the spread and combating the mortality of many of the contagious diseases. Yet with our present knowledge all opinions of bacteriologists, and especially those from some of us whose facilities are limited for various reasons, must not be accepted as infallible. The clinician who can use those means himself has infinitely greater advantage in arriving at results in prognosis and diagnosis by comparative methods and existing facts than have the clinician and bacteriologist independently of each other, when only the former sees the case and the latter the pathological specimen. Smears and membranes were examined microscopically, and these, together with the clinical features presented, did not satisfy me that my cases were diphtheria. I forwarded specimens to Mr. Alfred L. Beebe, Ph.B., of the New York City Board of Health, whose courtesy I acknowledge for the examinations he kindly made for me and the report herewith appended.

Dr. S. W. S. Toms, Bellport, L. I.:

Dear Doctor: I have carefully examined the cover-glass preparations which you left with me yesterday, and have also had Dr. Park examine them. I find a number of bacilli, evidently not those of diphtheria, numerous cocci, and a moderate number of bacilli which decidedly resemble true diphtheria bacilli, but are not sufficiently characteristic to admit of a definite decision as to their character. Dr. Park agrees with the above.

Sincerely yours,

Alfred L. Beebe.

It is much to be regretted, cultural or inoculation experiments could not have been conducted at the time. These were not deemed necessary, however, because of the clinical features and the evidence I had of the lack of contagious elements as demonstrated by the families where little or no heed was given to my warnings of its possibility. Despite my earnest endeavors, I often found reckless disregard of them in many ways. The morphological resemblance of some of the bacilli found to those of true diphtheria were doubtless those which have been described by Welch[1] and Abbott,[2] whose cases were almost identical with those of mine.[3] Moreover, the essential characteristics of the Loeffler germ, viz., *its virulency and its specific infectious nature, were wanting.*

Attempts at thorough disinfection of the sick-room and clothing miscarried, yet spread of the disease was not noticeable, with one exception; and *in that case the original cause or source of the primary case remained.*

The results of Hofmann,[1] showing the pseudo-diphtheria bacillus is without virulency, *although its identity with that of the Klebs-Loeffler bacillus was not distinguishable*, have since been confirmed by Roux and Yersin,[2] Escherich,[3] Park,[4] and others.

"If we review the remaining literature of this subject, we find some investigators have been led by the results to adopt views similar to those of Roux and Yersin, others to those of Escherich, and still others forced to content themselves with the position of Hofmann, viz., that we are not yet in a position to affirm whether all these bacilli are of one or of different species of bacteria."[5] "The bacilli found, when studied in pure culture, differ somewhat from each other. The majority were identical in all their characteristics with the Loeffler bacillus, except to their lack of virulence."[6]

As the microscopical evidence leaves the burden of proof in favor of non-malignancy and slight infectiousness, I briefly review the clinical facts, citing, by the way, the apparent etiological elements that seem to have a very noteworthy share in this connection:

First.—The absence of marked or profound constitutional toxemia, prostration, cardiac complications, albuminuria, abortion, or local sequelæ other than paralyses.

Second.—The *de novo* origin of each case. As there is positive evidence against the suspicion of contagion and infection of one from another, through the milk, food supply, or water, or that the disease was brought here from an infected community; and, furthermore, there has not been a case of diphtheria here in many years, and none of the cases stood even the remotest opportunity of exposure to a previous case of the kind, or of diphtheria. The disregard of quarantine did not spread the disease. "In the 350 cases of pseudo-diphtheria investigated, it did not seem that secondary cases were any less liable to occur where the primary case was isolated than when it was not."[7] Conditions existing at the time were very suggestive to my mind as bearing directly upon the cases, and were, in the main, the specific infec-

tious factors, viz., the exposure to fetor of putrefaction, decomposition, and fermentation from filthy outhouses, sinks, and cesspools.

Sewer-gas is responsible for infection of various kinds, especially the septic, which is well accepted by those who have seen the lessened mortality in institutions where there are no sewers and sanitary(?) plumbing—so-called. The Sloane Maternity is a notable example, and also the results in the pavilions of the Woman's Hospital, in New York City, as compared with those of the main building. At the time these cases occurred, the atmospheric conditions were peculiarly favorable to fermentative and putrefactive processes—a high temperature during the day, cool nights, and very high percentage of humidity. Fungi and their congeners—molds, etc.—grew prolifically, and the effluvia at night from outhouses and cesspools, commingled with the vapors of dampness, were all-pervading in localities where some of these cases existed. The classic clinical features that have been heretofore laid down in works of authority as distinguishing landmarks between true diphtheria and its associates have been shown by bacteriological research to be common to both. A certain general relation, however, does exist between the extent of local involvement to constitutional symptoms, but this is not invariable. It is still generally regarded by very eminent authorities that paralytic sequelæ are pathognomonic of true diphtheria. Bourges,[1] however, has demonstrated to the contrary, the prevalent belief notwithstanding:

"The writer calls attention to the fact that paralysis of the soft palate is not exclusively due to diphtheria, inasmuch as it occurs after typhoid occasionally; and some older authors have admitted the possibility of its occurrence after angina not of diphtheritic origin. The following case is reported: A seven-year-old boy had a pseudo-membranous angina, lasting seventeen days. Bacteriological examination demonstrated the absence of Loeffler's bacilli and of streptococci. The mother was infected, and her throat was also negative as regards the diphtheria bacilli and streptococci. Fifteen days after the disappearance of the pseudo-membrane, the child developed a convergent strabismus, followed in a few days by paralysis of the soft palate and then by an incomplete paraplegia, lasting one month. The development of these symptoms accords perfectly with that of diphtheritic paralysis, in spite of the positive absence of the specific bacilli."

[1] *Rev. in Rev. Mens. des Mal. de l' Enf.*, Tome xiii., No. 6; quoted *Arch. Ped.*, 1896.

It is significant that there was no mortality in this series of cases where no specific line of treatment was followed, that employed being purely symptomatic; no complications occurred, and the only sequelæ were paralyses. The recognition and differentiation of pseudo-membranous anginas are chiefly due to the investigations of Loeffler, Abbott, Martin, Beebe, and W. H. Park, and by others quoted by him. An analogous form of this disease, if not identical, has been recently described by Tidey,[1] as occurring in Switzerland in overcrowded and unsanitary hotels, which he has called "septic tonsilitis."

PRACTICAL INFERENCES FROM CLINICAL OBSERVATIONS IN LATERAL CURVATURE OF THE SPINE.[2]

By A. B. JUDSON, M.D.,
OF NEW YORK;
ORTHOPEDIC SURGEON TO THE OUT-PATIENT DEPARTMENT OF THE NEW YORK HOSPITAL.

In a majority of the patients affected with lateral curvature of the spine it becomes evident at the very first examination that the curvature and rotation are diminished when the weight of the upper part of the body is removed from the vertebral column. This weight may be removed by causing the patient to lie down or to suspend the body by the hands. When the patient is hanging from an overhead bar the deformity largely or entirely disappears. The curved line of the spinous processes partly straightens itself, and the lateral prominences, caused by rotation, partly subside; and when the patient releases the bar these elements of deformity reappear. These changes occur with the repeated use of the bar in a sudden and striking manner. They are also seen when the patient alternates between standing and recumbency. If the patient lies prone the spinous processes arrange themselves in a comparatively straight line, and the shoulders and hips approach symmetry. But when the erect position is resumed deformity returns in full force. Doubtless the same alternations occur with the supine, as well as the prone attitude, but they are not, from the nature of the case, then visible.

It is an interesting question whether spinal curvature and rotation can occur in a child whose attitude is absolutely uninterrupted recumbency, whose body has never been either actively or passively placed in a vertical position. If we say that the downward pressure of the head and the

[1] Tidey, *The Lancet*, December 14, 1895.

[2] Presented at the Tenth Session of the American Orthopedic Association at Buffalo, N. Y., May, 1896.

upper extremities is the immediate cause and that some, as yet unexplained, inability to properly sustain this weight is the indirect cause, we may be right in the supposition that absolute recumbency would be a preventive of lateral curvature. However this speculative question may be viewed the facts above recalled will surely furnish useful hints for the treatment of this deformity in a growing child. "As the twig is bent the tree is inclined" is a proverb applicable here. It follows that suspension and recumbency are two attitudes which should be prescribed, and the more time given to them the greater is the advantage to be gained from the growth of the patient. In suspension there should be no muscular effort beyond that required to keep the fingers flexed on the suspension bar, and in the meantime the body should swing gently, as a means of timing the suspension, seven vibrations, backward and forward, measuring one-quarter of a minute, which is commonly sufficient for each effort. Recumbency should be practised several hours daily, the position being supine, with an air-pillow so placed under the back as to maintain lordosis, and this should be observed so far as it is practicable at night.

Continuing our observations, it is seen, sooner or later, that fatigue or general weakness increases the deformity. If the patient comes in after a long walk or a tiresome journey, or if she is suffering an indisposition, the deformity is greater than it would otherwise be. So that if the patient is pale and tired examination will reveal more than the customary curvature and rotation; while, on the other hand, if she is not tired and is sustained by good sleep and digestion, the general well-being will find expression not only in the face but also in a diminution of the curvature and rotation.

The fact that the intervention of general fatigue increases the deformity is in accord with the view that one of the causes of lateral curvature is muscular failure to hold the spine erect under its natural burden. A sequence of causes may be arranged as follows: Diminution of the capacity of the chest is caused by rotation; rotation is caused (1) by the comparative wide lateral excursion of the bodies of the vertebræ, while the processes are hindered from wide lateral mobility by their entanglement in the posterior parietes; (2) by the curvature; the curvature is caused by failure of the muscular system of the spine to hold the vertebral column erect under its natural burden; failure of the muscles to do their duty is caused by defective innervation; the cause of defective innervation is as yet conjectural.

Whatever may be thought of this arrangement of factors, practically we may accept a hint from the observation that fatigue accentuates the deformity. Throughout the growing period over-exertion should be avoided. The child should not be told to "sit up straight," but rather to lie down. The recumbent position should be often taken and for long periods. Moderation should be the rule in all active amusements, and in all the duties, physical and mental, which fall to the lot of the child at home and at school.

Continuing our clinical observations, we become aware of the fact that the chest is expanded during suspension. This attitude expands the chest with as much directness as manual traction and counter-traction enlarge the cavity of a pair of bellows. The anatomical and physiological reasons for this effect were originally stated by our Honorary Member, Dr. Henry G. Davis.[1] When suspension is practised the muscles, which pass from the ribs to the humeri, attach the sternal ends of the ribs to the suspension bar by the intervention of the arm, forearm, and hand, while the vertebral ends of the ribs are powerfully drawn downward by the combined weight of the body and the lower limbs, producing forced inspiration in a very positive manner. This position is an exaggeration of Sylvester's method for the resuscitation of the apparently drowned, in which the operator produces artificial inspiration by drawing the arms forcibly above the head. In suspension, however, the force applied is the weight of a large part of the body, and is much greater than can be applied by manual traction on the arms of a supine patient. The repeated and persevering application of this force may be reasonably expected in time to have a lasting effect on the size of the thorax and the size of the lungs, and further consideration will show that in this agent we have a method of directly opposing the deformity, of doing what we vainly try to do by the use of mechanical pressure. A brace is powerless to reduce rotary lateral curvature. Its application is injurious rather than beneficial. As the ribs are attached chiefly to the processes instead of the bodies of the vertebral column, the first effect of the lateral pressure made by a brace on the ribs is to increase rotation, and curvature, and contraction

[1] "On the development of the thorax by special exercises, as a prophylactic and remedial measure in phthisis and other chronic affections of the lungs." *American Med. Monthly*, March, 1858, pp. 161–173. "Conservative Surgery," 1867, pp. 283–307. These pages were reprinted with the title, "Curability of Pulmonary Consumption."

of the chest. With suspension, however, what we cannot do by pressure from without, we can do by over-filling or inflating the space within, by a forced development of its normal contents. The emphasis thus given to the value of suspension is increased by the consideration that improved respiration applies a stimulus to the general health and indirectly gives tone to the muscular system, whose failure is one of the causes of lateral curvature.

Our knowledge of the pathology of this affection is insufficient to determine its treatment, but clinical observation provides a rational ground for active and persevering treatment, with a certainty of preventing an increase of deformity and a prospect of improving the condition in favorable cases.

CLINICAL MEMORANDUM.

DEATH FROM GONORRHEAL RHEUMATISM.

BY JOHN A. HAWKINS, M.D.,
OF PITTSBURG, PA.;
LECTURER ON DISEASES OF THE RECTUM IN THE WESTERN PENNSYLVANIA MEDICAL COLLEGE.

THE following case is of interest chiefly from the rarity of not only the complication, but especially on account of the unfortunate termination.

F. L., aged twenty-two years, a clerk, presented himself November 3d, suffering from an acute gonorrhea. As the glans and urethra were in a high state of inflammation, I prescribed a mixture of potassium citrate and tincture of hyoscyamus internally, and instructed him to call again in three days. This he failed to do, but appeared a week later, and stated that he had been unable to come to the office at the specified time, as he had been out of the city on business, which proved to be an untruth. At this time he began to act a little peculiarly, but this was attributed to a desire on his part to conceal the supposed fact that he had been using some proprietary article and found it necessary to return to us, and make a business trip the excuse for absenting himself. At this visit he also complained of pains in different parts of the body, and he was given a prescription containing acetanilid, potassium nitrate, potassium bicarbonate, and hyoscyamin sulphate.

The next morning I was summoned hastily, and found him wildly delirious. The friends said they had heard him talking all night, but supposed he had brought a friend home with him. In the morning they found him in his room, and he had taken the furniture apart and thrown his jewelry into a cuspidor. During the night he had struck his head against the joists in the cellar while after coal, and wore quite a contusion on the right frontal region. His pulse was 130, and at first I supposed I had a case of hyoscyamin poisoning, as there was considerable midriasis; but on taking his temperature my suspicions were set at rest, as the thermometer registered 103° F. He complained of his wrist hurting him somewhat, and there appeared to be a little swelling. He was given the bromids of potassium and sodium, and bathed.

By evening he was less delirious, and the next morning was almost free from hallucinations, his mind wandering slightly at long intervals. He still complained of his wrist causing him great pain, and he was given oil of gaultheria and bicarbonate of sodium, thinking that perhaps the gonorrhea had nothing to do with the case, and that he was suffering from articular rheumatism. A few granules of morphin were left, with instructions to give him a granule (one-twelfth grain) every fifteen minutes until relieved. Delirium had about ceased by the third day, except at nights. An ointment of ichthyol was prescribed, and the bowels were kept freely moving by the use of calomel.

He continued in the same condition until the sixth day, when the sodium was discontinued and the oil of gaultheria continued alone. On the ninth day, as the delirium continued, the oil of gaultheria was discontinued, and he was given sodium bromid and sodium bicarbonate. On the twelfth day, I thought it advisable to put him on the sulphate of quinin, and, as the heart had gradually become weaker, he received some alcohol. This was stopped as soon as the heart returned to a good condition again. There had been no urethral discharge since the fever came on, and no local treatment.

About this time it was noticed that he was very hard to wake, and involuntary evacuations from the bladder and rectum occurred. He complained of no pain, except when the right arm was moved. The elbow of the same side also swelled a little, and became painful. From this time on there was little change, except that coma became more complete, the patient dying on the nineteenth day. The *ante-mortem* temperature registered 105.6° F., although it had at times during his illness registered between 98 and 103.5 F. The pulse became very rapid, reaching 170. The respirations were rapid and irregular, and later of the Cheyne–Stokes character. The pupils remained equal and about normal during the entire period of illness, after the first three days. At no time were there convulsive movements. As the urine was passed with the feces, and involuntary, and as the urine had been discharging pus, there was little chance for examining the urine, but I am satisfied it was due neither to diabetic nor uremic poisoning. At all times the heart-sounds were clear and distinct. No abscesses appeared on the patient. Nausea was never present. There were no paralyses.

I have been unable to ascertain the number of deaths recorded as having occurred from gonorrheal rheumatism, but the number is very limited. It is probable that more cases have occurred than is supposed, but that the medical attendant has, through apathy, or possibly the nature of the disease, failed to report the case under its proper name.

MEDICAL PROGRESS.

Celiotomy in the Newborn for the Relief of Hernia of the Umbilical Cord.—MARJANTSCHIK (*Centralblatt für Gynäkologie*, 1896, No. 13, p. 345), has reported the case of a woman, twenty-four years old, whose third child pre-

sented by the feet, and was delivered with manual aid. The placenta had to be expressed, and contained calcareous deposits. The child was asphyxiated at birth, but was resuscitated, after active efforts by swinging. Projecting from the middle of the abdominal wall was a hemispherical mass as large as an apple, whose upper margin corresponded with the ensiform cartilage, and the lower with the umbilical cord. Its base was surrounded by a dense band of cicatrix-like skin. The tumor itself proved to be composed of a sac with thin, translucent walls, overlying the liver. Into this sac entered the umbilical cord (amnion and Wharton's jelly). In addition to these tissues, the wall of the sac was composed of peritoneum. By means of manipulation, it was possible to restore the intestines through the opening and to partially approximate the margins. The size of the tumor was little influenced by crying on the part of the child. On the second day of life, the surface of the sac commenced to lose its translucency and to assume a yellowish-green hue. The condition was recognized as a hernia of the umbilical cord, and immediate operation was proceeded with. The amniotic layer of the sac was carefully dissected off, the vessels of the cord freed from the Wharton's jelly and ligated and divided, and the exposed peritoneum removed. The prolapsing viscera were held in place by means of compresses. The margins of the opening were freshened and then sutured. The operation occupied fifty-five minutes, and a dram of chloroform was required for anesthesia. After the operation, the upper and lower extremities of the child were deeply cyanotic, so that it was enveloped in cotton and surrounded by hot-water bottles. The utmost care was observed in the nursing. The child partook of sugar water and of milk with a little cognac, and emptied its bowels and bladder. Slight jaundice developed on the second day after the operation, but soon disappeared. The temperature pursued an irregularly high range, and death took place when the child was five days and fourteen hours old, amid signs of great weakness. The bandage was removed before death, and it was found that the wound was in excellent condition, with its margins firmly adherent.

Death Eighteen Hours After the Introduction of a Bougie into the Urethra.—Muller (*Centralblatt für die Krankheiten der Harn- und Sexual-Organe*, 1896, B. vii., H. 3, p. 137) has reported the case of a man, thirty-eight years old, with a history of gonorrhea in youth, who came under observation on account of some difficulty in micturition. He had previously been treated for stricture of the urethra. The urine was turbid, and passed in a small stream. A diagnosis of vesical catarrh, with moderate stricture of the urethra, was made, and to determine the degree of narrowing, metallic sounds were employed. A No. 21 conical instrument, with a long curve, was first gently introduced, with due antiseptic precautions, and an impossible obstruction encountered in the membranous urethra. With still greater care, a No. 23 sound was next used, but also without success. The examination was unattended with pain, and but little blood was lost. A prescription containing uva ursa and sodium bicarbonate was given, and the patient sent home. Three or four hours after the manipulations, and immediately upon taking his medicine, the patient was seized with vomiting and diarrhea, followed by chill, restlessness, general prostration, pains in the chest and in the sacral region, and excessive thirst. Eighteen hours after the use of the bougies the patient died, amid symptoms of cardiac failure. Upon *post-mortem* examination, the heart was found to be slightly fatty and the lungs edematous. There existed cloudy swelling of liver, spleen, and kidneys. Portions of kidney were put aside for histologic examination, to determine if nephritis existed, but were inadvertently lost. The ureters and pelves of the kidneys presented no abnormality. A tight circular stricture was found involving the membranous urethra, and, close by, several diverticular depressions of the urethral mucous membrane, one of which appeared to have been recently eroded. Copious greenish pus escaped from the prostate gland. The mucous membrane of the bladder was in a catarrhal state; the viscus contained a small amount of turbid urine. The opinion is expressed that the fatal issue in the case reported is to be attributed to an acute nephritis, induced, perhaps, through the introduction of pus from the prostate through the erosion in the urethra.

Post-mortem Cæsarean Section, with Delivery of a Living Child.—Erdheim (*Centralblatt für Gynakologie*, 1896, No. 14, p. 377), has reported the case of a woman, thirty-two years old, in the sixth or seventh month of pregnancy, in which tracheotomy was performed for the relief of grave symptoms resulting from the compression of an enlarged thyroid gland. Partial relief followed the operation. On account of the retrosternal situation of the goiter, its extirpation could not be considered, and a course of treatment with thyroid tablets was accordingly instituted. The condition of the patient seemed improved, when suddenly copious hemorrhage took place from the tracheal wound, and soon terminated fatally. As the woman had now reached the seventh month of pregnancy, and the movements of the child were perceptible, immediate Cæsarean section was undertaken and successfully effected. The child corresponded in size and weight to the period of the pregnancy, and though moderately asphyxiated, breathed freely after slight swinging to induce artificial respiration. It also took some liquid nourishment offered it. It lived, however, only 13½ hours, death resulting from asthenia.

Tabes Dorsalis Without Incoordination.—Grandmaison (*Médecine Moderne*, 1896, No. 20, p. 156) has reported the case of a man previously well, who, at the age of sixty-one years, was affected with impairment of vision progressing in the course of six months to complete blindness. The optic papilla was found atrophied, and the change was believed to be tabetic. The patient also suffered from time to time from intestinal tenesmus, with an imperious desire to evacuate the bowels. Examined seven years later, it was found that the knee-jerks were entirely abolished, the rectal crises having meanwhile continued. In the further progress of the case, arterio-sclerosis developed and symptoms of myocarditis made their appearance.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

REVIVAL OF THE OLYMPIC GAMES: IS IT WISE?

IN spite of the many broken bones and disfigured faces, to say nothing of the many fatal accidents that have attended the game of football in recent years, the popularity of athletic contests seems steadily on the increase. From the simple and healthy competition of class rivalry in our colleges, the spirit of emulation spread to intercollegiate games, in which the champions of the individual colleges met to contend with all the tremendous energy and fury of mortal combat. To this spirit of rivalry has gradually been added the incentive of international contests of more or less celebrity, such as the Henley regatta and the international athletics. And out of these arose finally the idea of reviving the old Olympic games.

This idea, once conceived, needed no arguments to bring conviction to the athletic world. It appealed irresistibly to all lovers of manly sports. The very name Olympia brings before the imagination forms of classic heroes who met their opponents in the arena in honorable, manly contest and carried off the palm of victory amid the plaudits of the assembled thousands. Nor can we resist the conviction that the ambition thus aroused to gain the coveted prize was the means of bringing the human form divine to its highest development, and that in the ancient Greek we have the ideal perfection of that physical beauty.

The result of the suggestion was that in April last an international contest, known as the Revival of the Olympic Games, was held in the ancient stadium at Athens. Ten of the leading nations of the earth were represented, and we as Americans were justly proud of the fact that the United States carried off more prizes than any other nation. We exulted in the success of our champions, and proclaimed the glories of the Olympic games in reviving the spirit of chivalry, awakening national pride, and consolidating peace and friendship among nations. We rejoice too in the stimulus thus given to athletic sports, and the cultivation of physical prowess and vigor.

This is all very well in its way, but the question arises what is the effect of all this training and effort on the individual contestant? What does the physiologist say? Is it true that these benefits are all obtained only by the sacrifice of him who takes the palm?

The Hospital, in an editorial on the physiologic cost of a boat-race, suggested by the recent Oxford-Cambridge race, says:

"Speaking as judicially as is possible, a physiologist cannot but express the conviction that every man in the two boats, except, perhaps, the two coxswains, must have been, to some extent, injured. In a definite number of cases, the injury is lifelong to individuals; and in every race every man can hardly fail to be more or less of a sufferer for a longer or shorter time. Such is the game, and such is the candle."

These arguments do not apply to all athletic games to the same degree, for in none of them, except perhaps the long-distance run, is the physiological strain kept continuously at the highest possible pitch of tension for so long a time. But the disastrous effects of overtraining and the supreme effort of the contest apply with equal force to all.

Train as systematically, as methodically, as scientifically, as he may, the supreme moment of the final struggle is, as a rule, too great a strain

for the heart or the blood-vessel, and the record-breaker then and there too often puts the seal of a shortened existence upon his life. The records of insurance companies show that a surprisingly large percentage of the college athletes—the heavyweights of the football team, the sprinters in the race, or the stroke-oars of the crews—have a weakened heart or a diseased kidney, or both.

Recognizing, then, the fact that the contest is deleterious to those who take the active part, is it fair to encourage the college athlete to enter the lists and take upon himself these risks? These games are restricted to amateurs, and amateur athletes, in this country at least, are to be found almost exclusively among college students. The amateur is not like the professional, who has no ambition in life beyond his athletic prowess. The contest, to him, is but an incident in his preparatory career. If this training and this experience fitted him the better to meet the demands of his future career, it would certainly be a desirable preparation; but the average college athlete sooner or later enters one of the professions, and has nothing in his daily life to keep his over-developed muscular system and his overtaxed heart and kidney in condition. He is less able to meet the nervous wear and tear of a sedentary life than his more equally balanced, but less athletic comrade.

From the standpoint of the physiologist, it must be conceded that the college athlete is too young and immature to subject the functions of nerve and muscle and heart to the strain of a contest where so much is at stake as the world's record, the medal, and the palm of a great international contest like the Olympic Games.

GENITO-URINARY DISEASES. RECENT ADVANCE IN THE KNOWLEDGE OF CYSTITIS.

Upon no branch of medical knowledge has bacteriology thrown more light than upon the various inflammations of the bladder and of the genito-urinary tract. Until ten years ago our ideas as to the etiology and pathology of cystitis were, judged by the standard of to-day, crude and inaccurate. But since that date an era of light has set in. In the early days of the bacterio-pathologic research into the phlegmasiæ of the urinary tract, between thirty and forty varieties of microbes were found and were regarded as more or less potent etiologic agents. The result of the discovery of this vast genito-urinary flora was, in the main, bewilderment of mind, and no precise and sharply-defined scientific knowledge was then gained. As time went on, however, the subject became more simplified; many supposedly harmful microbes were found to have little or no pathologic influence, others were proved to be harmless saprophytes, still others of accidental occurrence; while many were found to be simply different varieties of a parent stock. In these studies Guyon and his disciples have taken front rank but other investigators are entitled to much credit for the classification and amplification of the knowledge which we now possess. It is but fair to state that the most complete portrayal of cystitis has been made by Melchior, a Dane, (*Cystite et Infection Urinaire*, Paris, 1895), and that the value and importance of his work in the French translation has been much enhanced by notes and comments by Guyon and Hallé, who are in accord with him on all the main issues. Melchior's essay is based on thirty-five cases of chronic cystitis carefully studied by him clinically, microscopically, and bacteriologically, and it has the further advantage that the essential points of about two hundred cases observed by many writers and experimentors are given in a critical analysis. From these storehouses of knowledge, therefore, much can be gained and various forms of cystitis may be traced on broad lines.

To approach the study of cystitis intelligently, two considerations relating to old ideas present themselves. In the first place it must be remembered that advanced thinkers and experimenters utterly repudiate the existence of the so-called catarrh of the bladder. Such a condition is a myth, bladder inflammation being really a suppurative process of varying degrees of severity, and in its mild form (which is generally called catarrh of the bladder) the tissue-exudate is pus and not mucus. In the second place the old idea that ammoniuria, or cystitis with ammoniacal urine, presents the type-form of bladder-inflammation is almost wholly incorrect, since ammoniacal decomposition of the urine is, in the vast majority of cases, secondary to other pathological conditions. As a corollary

of the last postulate it may be stated that in the majority of cases of cystitis the urine is acid, and ammonia is not present in it. Fetid urine is not necessarily alkaline nor ammoniacal.

In the development of cystitis certain underlying conditions of mucous membrane must exist in order that a condition of receptivity or susceptibility to microbic invasion may be present. In retention of urine, particularly when of long standing and severe from any cause, the bladder-tissues become much distended and may be more or less injured, and in this altered condition of their nutrition they cannot, as they may when normal, resist invasions by micro-organisms. Then again, in chronic gonorrhea the urethro-cystitis which is not infrequently present, becomes a focus from which the whole cavity may be infected. Clinical observation has shown that this susceptible condition or tendency to bladder-inflammation varies in different persons; some patients seem exceedingly susceptible, others less so, while still others are almost immune.

By a remarkable concensus of statement it seems that the most frequent pathologic agent in cystitis is the *bacterium coli commune*, which, in thirty-five cases examined by Melchior, was found in sixty-six and two-thirds per cent. Next in order is the *streptococcus pyogenes*, which Melchior found in four cases. Cystitis depending upon these microbes which usually are found singly in a case, and exceptionally in combination, may present varying clinical phases, but the urine is usually fetid in odor and acid in reaction. Upon long standing outside the body or in cases of retention with overflow and long-standing residual urine, Hallé and Guyon think that the *bacterium coli commune* may exert a mild action in decomposing urea and in developing ammoniuria. Melchior, however, is not of this belief.

It seems that the most energetic and dangerous microbe found alone or in combination with one or both of these fore-mentioned micro-organisms is the *proteus* of Hauser. This bacterium exerts an energetic action in the decomposition of the urea, and by means of the ammonia, which it produces without any adjuvant influence, may cause inflammation in a perfectly healthy bladder. In other words, without any tissue predisposition, this microbe may cause cystitis by reason of the chemical irritant which it can produce in urine. Cases of cystitis due to the *proteus* of Hauser alone or in combination with the *bacterium coli commune*, or the *streptococcus pyogenes*, are always those of exceptional gravity and in these urinary infection is frequent and often deadly, and ascending invasion of the ureters and kidneys is quite a common complication.

Though Melchior found in the purulent ammoniacal urine of three cases the *staphylococcus ureæ liquefaciens* the exact essential causative relation of the microbe to cystitis is not yet clearly demonstrated, since it was found only once in pure culture. It possesses, as does the *diplococcus ureæ liquefaciens*, the power of decomposing urea and producing ammoniuria. These two microbes, together with the *strepto-bacillus anthracoides*, which were first described by Melchior, certainly are pathologic to the bladder tissues, but further observations are necessary to clear up the doubt which is warranted, as to their being the primary agents of infection.

On the question of gonorrheal cystitis Melchior's observations are very interesting, since they enable him to definitely state that he has in such cases found the pathologic agent to be the gonococcus. This experience is, in my judgment, exceptional, and Hallé, in a footnote, undoubtedly states the correct facts when he says that in general gonorrheal cystitis is due to secondary infection, but that in a minority of cases the gonococcus is the cause of the inflammation.

No doubt can now be entertained of the fact that the bacillus of tuberculosis may be the active cause of a severe form of cystitis in which the urine is purulent, acid, and sometimes bloody. Both Melchior and Hallé rightly insist that great care and technical skill are demanded in the examination of the urine for the discovery of Koch's bacillus, which was found seventy times in two hundred examinations by Hallé.

Though we know that the genitals of males and females, even those of strictly cleanly habits, swarm with microbes, innocent and pathogenic, it is interesting to learn that by careful gathering and culture Melchior found the *bacterium coli commune* and the *staphylococcus pyogenes aureus* upon the prepuce, in the vulva and vagina, and upon the lips of the meatus, both male and female. When to

this knowledge is added the well-demonstrated fact that in the normal, and particularly in the diseased urethra, several forms of pathologic microbes are constantly present, it can readily be seen how easy it is to set up an inflammation by the conveyance of these micro-organisms by means of instruments into a susceptible bladder. The necessity for great care and antisepsis in operations, both minor and major, upon the male and female bladder is hereby forcibly brought out, and well may Melchior emphasize the warning to *never provoke a cystitis*.

The etiology of cystitis may be summed up in the following manner: The external genital and urethral canals, male and female, teem with microbes which, if carried by any means into a bladder vulnerable to infection, may produce cystitis. The most constant infecting agent is the *bacterium coli commune*, and next in order certain streptococci and perhaps staphylococcocci, all of which produce severe forms of cystitis. The *proteus* of Hauser primarily or secondarily to one or several of the above-mentioned microbes may cause a severe, even rapidly fatal, form of cystitis. The gonococcus and the bacillus of tuberculosis are potential agents in bladder inflammation in a smaller number of cases.

Though there may be some truth in the claim set forth by Reymond (*Cystites Consécutives à une infection de la Vessiè à travers ses parois, Annales des Mal des organ Gén Urin*, April and May, 1893) that cystitis primarily may be caused by microbic invasion of the bladder tissues from without, *e.g.*, from some morbid focus in the pelvis or connected with the rectum or intestines, no authoritative statements can now be made.

Robert W. Taylor, M.D.

ECHOES AND NEWS.

The death of Sir J. Russell Reynolds occurred at his home in London on May 29, 1896. He was born in 1828, and began the practice of medicine in 1852.

The International Congress of Dermatologists will convene in London August 4th next. Among those expected from America at this session are Drs. Duhring, White, Bulkley, Keyes, and Fox.

Dr. Robert Abbe has resigned from the Professorship of Surgery in the New York Post-Graduate Medical School and Hospital.

Reports of the increasing spread of the bubonic plague in China continue to come with every steamer arriving in San Francisco from Oriental ports.

Dr. M. Allen Starr of New York, has been elected president of the American Neurological Association for the ensuing year. The meeting of this Association held last week in Philadelphia was one of the most successful in the history of the organization. The next session will be held at Washington in 1897, in connection with the American Congress of Physicians.

The American Association of Genito-Urinary Surgeons closed its annual meeting at Atlantic City June 3d. The officers elected for the coming year were Claudius H. Mastin, M.D., of Mobile, president; F. S. Watson, M.D., Boston, vice-president; W. K. Otis, M.D., New York, secretary; L. Bolton Bangs, M.D. and J. A. Fordyce, M.D., New York, members of the council; R. W. Taylor, M.D., New York, delegate to the international convention, and E. L. Keyes, M.D. alternate. The next meeting will be held in Washington, D. C.

Dr. Homer Virgil Milton Miller died at his home at Rome, Ga., on May 31, 1896. He had spent a most active life of eighty-two years and at his death was Dean of the Atlanta Medical College. Besides merited prominence as a practitioner and teacher of medicine Dr. Miller has held a prominent place among the Southern statesmen since the ante bellum days and served as United States Senator from Georgia in 1868.

Dr. A. L. Metz, who was appointed temporary Professor of Chemistry to fill the vacancy in the Medical Department of Tulane University, New Orleans, caused by the death of Professor Joseph Jones, has been elected permanently to the chair.

Three doctors, belonging to the medical staff of the almshouse on Blackwell's Island, have been arrested on a warrant charging them with stealing and appropriating to their own use drugs and supplies furnished to the almshouse by the city. A fourth doctor, whose name was included in the warrant, went to Canada several weeks ago. By the arrest of the three prisoners it is thought that a systematic stealing of supplies, which is said to have been going on in the charity institutions of the city for several years, will be brought to a termination. If the suspicions of the authorities be correct, thousands of dollars' worth of drugs and medicines, paid for by the city, have been appropriated to the use of doctors attached to the staff serving on the Island. Expensive drugs, bandages, and other appliances used in the medical and surgical wards of the city institutions have disappeared by wholesale. The defense is that custom has sanctioned the taking of these articles, which are regarded by the doctors as perquisites for their labors during their terms of service on the house staff. The value of the articles taken was estimated at $500. Taking the four doctors as a factor in calculation, and estimating their perquisites at $125 a year each, the outcome is astonishing. Now, fifty doc-

tors leave the various institutions every six months, or one hundred a year, and, if everyone fitted himself out with a kit of the same value the annual expense would amount to $12,500. It is highly improbable that any such custom has prevailed.

AT a meeting in Albany on June 1st of the New York State Lunacy Commission, with the superintendents of State Hospitals, the plans for an addition to the Ward's Island Hospital, to accommodate 150 patients, and a building to be erected at Center Islip for 100 patients, were accepted, as were also the plans for the groups of cottages to be erected at King's Park in connection with Long Island State Hospital.

THE Queen has reappointed Mr. Thomas Pridgin Teale, M.B. Oxon., F.R.C.S. Eng., a member of the General Council of Medical Education and Registration of the United Kingdom. This will be the fifth term of five years' service for Mr. Teale.

IN Harris and Beales on "Pulmonary Tuberculosis," a recent publication by the London house of H. K. Lewis, there is given a remarkable instance of the arrest and cure of the tuberculous process by the advent of an acute disease. Two young men in the last stage of pulmonary consumption were attacked with virulent smallpox; both recovered, and at once the pulmonary symptoms disappeared. The patients gained flesh and strength and are now the living images of health. In another case an attack of acute rheumatism was followed by disappearance of the symptoms and signs of advanced phthisis.

THE following preambles and resolutions were unanimously adopted by the American Pediatric Society, which met in Montreal, Can., May 27, 1896, and signed by most of the members present:

Whereas, A bill is at present pending before the Congress of the United States entitled, "An Act to Prevent Cruelty to Animals in the District of Columbia," which curtails experimentation upon animals, and would put a stop to medical research; and

Whereas, It is very probable that such legislation would influence greatly similar legislation in the various States which would prevent the advancement of medical science and of medical education; and

Whereas, Such legislation would be very prejudicial, and is not called for by any existing facts of cruel experiment, as the advocates of the bill themselves concede so far as the District of Columbia is concerned; be it

Resolved, That the American Pediatric Society, now in session at Montreal, presents these resolutions as a memorial to Congress and enters a protest against the enactment of such legislation, declaring it to be needless and injurious.

Resolved further, That a copy of these resolutions be sent to the journal of the American Medical Association, and to the other weekly journals.

IT appears that only recently have our English friends been brought face to face with the question of female doctors and their relations to the medical profession. By a substantial majority they were last month excluded from membership in the London Pathological Society. The matter of the indelicacy of discussing certain subjects in their presence being the only shadow of an excuse offered for this decision. Strong opposition with threats of a "boycott" on the part of the students of the Irish College of Surgeons and Catholic University has followed the appointment of Miss Dickson as examiner in gynecology. She is a doctor of the highest attainments in this specialty, a Fellow of the College of Surgeons and in every way eminently suited for the position unless her sex should be considered the disqualifying element.

AS has been confidently expected, the warmer weather has increased the virulence of contagious diseases among the Spanish troops in Cuba. No reliable statistics are published but it is confidently asserted from observation that yellow fever is daily increasing the death rates. Smallpox is also raging in many parts of the island. One town is known to have suffered ninety-six deaths from the latter disease during the past month.

IN a recent letter to *The Lancet*, an English optician uses the following expressions which convey a few of the good thoughts of his communication: "I think the majority of opticians—those, at least, who have a due sense of the responsibilities involved—look forward hopefully to a time when people will go as naturally to the medical practitioner for advice on eye and sight troubles as they do now for defects of hearing. I think, too, they are doing good work, each one according to his opportunities, toward bringing that time about. No encouragement should be given to proposals for measures, legislative or other, such as have recently agitated the State of New York. Feelings of rivalry should be restrained, and the issue left to easy and natural development."

THE WOMAN'S MEDICAL COLLEGE OF BALTIMORE has lengthened its annual course to eight months (October 1st to June 1st). The following appointments have been made in the faculty: R. Tunstall Taylor, M.D., Professor of Orthopedics; Thos. C. Gilchrist, M.R.C.S., Professor of Dermatology; Henry P. Hynson, Ph.G., Professor of Pharmacy; G. Milton Linthicum, M.D., Professor of Physiology; Kemp B. Batchelor, M.D., Associate Professor of Obstetrics. A Chair of Mental Diseases has been added; also departments of Bacteriology and Embryology. Professor Claribel Cone has been elected to the Board of Trustees.

THE number of human lives sacrificed by the drinking of carbolic acid, either accidentally or intentionally, is becoming so great that it will evidently be impossible to allow the free sale of it to continue. A London paper states that in a single week no fewer than nine persons met their death in that city from this agent.

AN entertaining writer in the Johns Hopkins Hospital *Bulletin* believes that he has found a classification of surgeons under the following heads: There are two distinct tendencies observable in that wonderful wave of recent surgical progress of which we are so justly proud

as a profession. One is the perfection of the technical part of our art, the improvement of methods of operation, the invention of new instruments, the elaboration of sutures and suture materials, and the extension of surgical procedures to every process of disease, from defective cerebral development to endocarditis. The other is the clearing up of the origin and causes of surgical diseases, the less brilliant but more thoughtful study of processes by the bedside and in the laboratory, the linking together of diseases in a coherent scheme, the investigation of the philosophy of pathological action and its relation to physiology. Both are necessary to progress, but the former alone produces the "mere operative surgeon," as one of our masters in surgery terms him, the instrument-inventor and namer, the "button-maker," the fee-collector; while upon the latter only can be based true progress, permanent and rational advances, broader knowledge, and that nobler type of the surgical mind, that of the true fathers of the art, who are thinkers rather than operators, and philosophers as well as pathologists.

VERY soon after the profession of London had received definite proof of Dr. Jenner's great discovery, proffers were made to him to take up his residence at that city. It is reported that Mr. Cline urged him to settle in London, promising him an income equivalent to $50,000 per annum as the result of his practice. To this, however, his deliberate reply was: "Shall I, who, even in the morning of my days, sought the lowly and sequestered paths of life, the valley, and not the mountain; shall I, now my evening is fast approaching, hold myself up as an object for fortune and fame? My fortune, with what flows in from my profession, is sufficient to gratify my wishes; indeed, so limited is my ambition, and that of my nearest connections, that, were I precluded from future practice, I should be enabled to obtain all I want. And as for *fame, what is it? A gilded butt, forever pierced with the arrows of malignancy.*"

BEFORE the Medical Club of Vienna, Dr. Herz has recently introduced the subject of the nail-pulse which has recently been advocated in many quarters as a more delicate method of diagnosing morbid conditions of the circulation. For a long time the sphygmograph was the only instrument in which we trusted for hematic information. This was succeeded by the plethismograph; later, Ruedl of Bern, introduced the flammentachygraph, and now we are confronted with the onychograph as the most delicate instrument for hematic curves, as it faithfully exhibits the movements in the capillary vessels. When the capillary arteries and veins contract, the instrument shows a low curve; when dilated, the pulse curve is high. From this curve, with the assistance of the respirations, the condition of the brain can be presumed. In the case of icterus the capillaries are dilated. This state is also present during the rigors of malaria, as well as in aortic insufficiency. In mitral defects a nail-pulse could not be obtained. The instrument can unhappily only determine the condition of the capillaries in the digits.

A PICTURE of Mentone, as it was forty years ago and as it is now, is thus presented by the *Medical Press and Circular*: "At that earlier date Mentone was a happy village in France, where lived peasantry happy on their farms and in their superb physical state, conditioned by the climate. It was discovered that the region was a most healing one for consumptives, and it became the Mecca for the unfortunates of Europe so stricken. The inhabitants abandoned their farms to wait upon the strangers. The strong healthy women forsook their dairies and became the washerwomen of the consumptives' clothes. No precautions were taken; the disease was not then understood as now, the theory of the tubercle bacillus not having been discovered. The place to-day is bacillus-ridden, a pest hole, death itself. The hitherto strong inhabitants are emaciated, a coughing, bleeding people, filled with the germs of consumption. The soil and air are both contaminated with the tubercle bacilli. It is no longer a health resort." The same fate, it is believed, awaits many other similar localities unless active measures are taken to destroy all germs. This will be a most difficult task, because consumptives themselves, as a rule, are not thoughtful of the danger they spread, or of the rights of others. They should bear in mind that if all others had been careful, they, too, might have escaped.

A PETITION, signed by nearly two hundred members of the Society of Medical Phonographers, including the names of Lister, Wilks, and Heath, has been presented to the General Medical Council of England. This is a request that shorthand should be an extra optional subject for the preliminary examination of students applying to this Council. The evident utility of shorthand in the duties of a student, as well as a practitioner, makes it an almost indispensable aid.

THE LIVERPOOL LADIES' CHARITY AND LYING-IN HOSPITAL is now without a medical staff, and from the unanimous determination of more than two hundred professional men of Liverpool and its vicinity to resent the indignities heaped upon a former staff by the managing board of this hospital, none will soon be secured. If we are correctly informed, the difficulty arose over the instruction of midwives in the institution. Over these the medical staff were to exercise no control, and were expected to handle no obstetrical case unless it proved too complicated for these novices, the latter remaining in charge and accepting service, as it were, from the surgeons.

THE extremes to which some of the London hospitals have gone in forcing their claims for contributions on Hospital Sunday has brought severe criticisms upon them. Street soliciting, with the circulation of boxes, was bad, but processions and parades were apparently more than the public could endure.

THE EPIDEMIOLOGICAL SOCIETY OF ENGLAND has expressed its determination to found a medal in honor of Jenner, to be known as the Jenner Memorial Medal. It is to be awarded to persons who shall add to the knowledge of epidemiology and preventive medicine.

CHARLES S. LEACH, M.D., an English missionary, resident at Sfax, in Tunisia, North Africa, has been mur-

dered, together with his wife and a five-year-old son. His little daughter of two years was spared. Dr. Leach and his wife, who had previously been laboring in Algeria in connection with some American friends, joined the North Africa mission early in 1891. In the summer of that year they removed to Tunis, and after a time of Arabic study, with the assistance of other missionaries, began a medical mission there. A few months since, he requested the council of the mission to be permitted to open a new medical mission at Sfax, which is the second largest city in the country, and situated on the coast, about two hundred miles further south. He moved there with his family about the middle of March, and had been mainly occupied since then in getting the house and station into order. He wrote on April 27 that people were asking when he would open the medical mission, and that he hoped in a short time to do so. This massacre, which took place during the first week in May, is as yet unexplained, and well-nigh inexplainable, except on the grounds of mob violence. It would appear that Dr. Leach was on his own premises when the muderous deeds were done.

IN the days of the Republic, the medical profession in Rome was a mere fortuitous concourse of atoms, and it was not till the time of Augustus that it began to have anything like a corporate existence. The process of organization seems to have begun with meetings between the adherents of different medical sects for the discussion of their several doctrines—somewhat on the lines of our societies. These meetings were at first held wherever the disputants could find shelter—in the Temple of Peace, in the Palatine Library, in the gymnasia. In course of time, however, a local habitation and a name were found in the Schola Medicorum, on the Esquiline, which constituted what may be termed an Academy of Medicine, with offices, secretarties, archives, and all the rest of it. The ruins of this Academy were still to be seen in the sixteenth century, and from the descriptions of travelers who saw them, the Schola Medicorum must have been a handsome structure. Of all the paintings and sculptures which adorned it, the only thing that now remains according to M. Maurice Albert, is a mosaic, which is preserved in the Villa Albani. This represents a group of seven physicians, one of whom is probably Antonius Musa.

SOCIETY PROCEEDINGS.

TWENTY-FIRST ANNUAL MEETING OF THE AMERICAN GYNECOLOGICAL SOCIETY, HELD IN NEW YORK, MAY 26, 27, AND 28, 1896.

(Continued.

SECOND DAY—MAY 27TH.

The morning's exercises were opened by the President's address entitled,

TWENTY-ONE YEARS OF GYNECOLOGY AND OBSTETRICS. (SEE PAGE 630.)

by DR. WILLIAM M. POLK of New York.

DR. PAUL SÉGOND of Paris, presented in French a paper upon

THE TECHNIC OF VAGINAL HYSTERECTOMY,

which was interpreted by Dr. Henrotin. He presented vaginal hysterectomy, not as a panacea, but as one method adapted to a certain class of cases. The adominal method was preferable in all cases in which there was doubt regarding the existence of bilateral disease, because it gave opportunity for conservative work. It was extremely important to avoid the abdominal scar, especially in cases of fibroids, on account of the necessarily extensive incision required. All the steps of the operation in the vaginal method should be done under the guidance of the eye. The line of cleavage having been found, it was just as easy to separate from below as from above. In rare instances, it might be necessary to do an incomplete operation, but in these unusual cases the danger arising from excessive manipulation of the bowel counterbalanced the disadvantages of the incomplete operation when done from below. In 600 cases he had not met with a single hernia, hence, vaginal hernia could not be reasonably offered as an objection to this procedure. Dr. Ségond said that in these 600 operations he had wounded the bladder six times. This accident was most liable to occur at the time of the initial incision anterior to the cervix, or just as the operator was about to enter the adominal cavity. By pulling the cervix backward and forward the surgeon could determine the exact limits of the bladder, and by avoiding the use of the lateral retractors, the bladder should not be injured in the subsequent steps of the operation. He used a short retractor, held gently against the anterior face of the uterus. Where the rectum had been wounded, he had found that it healed easily and completely. The ureter was liable to be injured (1) when dissecting back the bladder and anterior vaginal wall; and (2) in the later manipulations for controlling hemorrhage. By making his circular incision, and then a lateral incision, and using care in dissecting up this anterior flap of the vagina, this accident could be for the most part avoided. He required his patients to stay in bed for two weeks, and unless there was some special indication, he did not change the packing for five or eight days. By using the instruments of Péan, and leaving them in position for forty-eight hours, hemorrhage could be ordinarily avoided.

DR. JOHN BYRNE of Brooklyn read a paper upon

THE RELATIVE MERITS OF TOTAL OR PARTIAL HYSTERECTOMY FOR CANCER OF THE CERVIX, BY ORDINARY METHODS, AND SUPRAVAGINAL EXCISION BY THE GALVANO-CAUTERY.

He said that one could hardly fail to be impressed with the gravity of vaginal hysterectomy after having witnessed its performance. He was of the opinion that it would have been better for women had the statistics of Price, Eastman, and others never seen the light of day. In studying the statistics of the subject under consideration in his paper, he had been struck with the very varying reports regarding primary mortality. In 1273 colpo-hysterectomies by 38 surgeons, the average primary mortality

was 14.6 per cent., and this, too, among expert operators. In the course of three years, 163 vaginal hysterectomies for cancer had been done in a single institution, yet at the end of three years only 25 per cent. were alive. Of these, 40, or 12 per cent., were said to be free from any recurrence of the disease.

Dr. Byrne then presented the results of his own experience in the treatment of cancer of the cervix by supravaginal excision performed with the galvano-cautery knife. Of forty cases that he had been able to keep under observation, the average period of immunity from recurrence was nine years. A most unpromising case had been operated upon twenty-one years ago, and was still in perfect health. He claimed the following advantages for his method: (1) Exemption from traumatism of parts supposed to be healthy; (2) an almost complete annihilation of the primary mortality; and (3) prolonged immunity from recurrence.

Dr. R. S. Sutton said that all surgeons occasionally met with what appeared clinically to be undoubted cancer of the cervix, and yet microscopical examination failed to confirm this diagnosis. According to his experience, when the diagnosis of cancer was beyond question, the disease recurred comparatively early, and he doubted if it made any difference whether the operation were done with the knife or with the galvano-cautery. The Paquelin was much more rapid in its action.

Regarding the treatment of fibroids, he would say at the present time that he preferred, in the case of small fibroids, to do an anterior colpotomy, enucleate the fibroid, and, whenever possible, return the uterus to the pelvic cavity.

Dr. J. E. Janvrin said that the discussion of cancer of the uterus had been limited by the author of the paper to cancer beginning in the cervix—only about one-fourth of all cases of uterine cancer. In a paper which he had prepared last winter, he had stated his ultimate results in sixteen cases to be 33⅓ per cent. absolutely cured, having been free from recurrence for periods varying from a little over three years to twelve years. As a rule, cancer patients suffer much less from the recurrences than from the primary disease.

Dr. W. H. Wathen of Louisville said that vaginal hysterectomy could often be done without any retractors, and it was seldom that more than one was needed. Where the disease was unilateral, it seemed to him that there was less danger and mutilation from the vaginal operation.

Dr. H. A. Kelly said that it was not possible by the vaginal route to decide as carefully regarding what structures could be saved. Carcinoma demanded such extensive dissection, that he thought abdominal section was the only effective method of dealing with this condition. He could see only one distinct advantage of the vaginal method, and that was that it was less dangerous if the aseptic technic were faulty.

Dr. Ernest Cushing said, that as the only two cases in which he had injured the ureters in the vaginal operation had been those in which the accident was attributable to the careless use of retractors, he was prepared to endorse what Dr. Ségond had said on this point. Where a patient was much exhausted by sepsis, and a collection of pus was readily accessible through the vagina, this was the proper route to select. He would not do the vaginal operation for the relief of disease of the appendages if the uterus were adherent.

Dr. Mann said that the selection of the route in cases of cancer should depend upon the exact site of the disease. The experience of many surgeons of repute had demonstrated that in cases of cancer of the cervix better work could be done by the abdominal route. In these cases, a very extensive dissection was required—such as could only be well done by abdominal section.

Dr. Thaddeus Reamy of Cincinnati, remarked that the arguments of Dr. Kelly on this subject appeared to him to be decidedly fallacious.

Dr. A. Palmer Dudley of New York, said that in Jacobs' method of operating through the vagina, it was necessary to use a retractor in order to prevent burning the tissues with the cautery. Where it seemed necessary in cases of uterine cancer to make the extensive dissections referred to by Dr. Kelly in order to remove the disease, it was his opinion that the patient was better off if left alone without operation.

Dr. Bache Emmet exhibited a special clamp he had devised to facilitate work which could not be done under the guidance of the eye. This clamp had long jaws, and by merely bringing together the distal ends of the blades, the latter were locked.

Dr. Florian Krug of New York, contrasted the discussion of to-day with that occurring two years ago. He said that in the present discussion he had not yet heard a dissenting voice regarding the propriety of removing the uterus in suppurative disease.

Dr. Ford of Utica, said that there were still some surgeons living who favored conservatism as regards the uterus. He was glad to see that the practice, originally advocated by Ségond, of extirpating the uterus in order to gain easier access to the diseased adnexa, had not found favor in this country.

Dr. Henry C. Coe of New York, said that he had become a pessimist regarding the treatment of malignant disease. It was well known that, even after the most radical and extensive operations for the removal of carcinoma of the breast, nodules of suspicious structure could be found by the microscopist beyond the supposed limit of the disease, and that in these nodules the disease recurred. Dr. E. C. Dudley had advocated the use of clamps in operations for malignant disease, on the ground that the resulting sloughing process destroyed groups of cells beyond the line of incision. If this were true, it was easy to believe that Dr. Byrne's method of using the galvano-cautery did possess a decided advantage over the use of the ordinary knife.

Dr. S. C. Gordon said he was in the habit of doing the vagino-abdominal operation in cases of carcinoma of the uterus, for the reason that he could more easily remove the vaginal portion of the cervix by the vaginal route. Regarding the operation for fibroids, he still maintained that the abdominal operation was the better

one. He could see little enough, he said, by that route, but much more than by the vagina.

DR. BAER of Philadelphia, said that if he could believe that the uterus was seriously diseased when there was extensive disease of the appendages, he would probably operate through the vagina, and extirpate the uterus, but as he could not convince himself of the correctness of this view, and as he considered it important to retain the cervix, he adhered to the abdominal operation.

DR. J. M. BALDY of Philadelphia, said that so far the only objection made to the abdominal route was the abdominal scar. Against this disadvantage he would place the shortening of the vagina resulting from vaginal hysterectomy. He had known it already to be the cause of much domestic unhappiness. The report from Dr. Ségond showed that the bladder, bowel, and ureters were much more frequently injured by the vaginal than by the abdominal route, and certainly in hands less skilled than those of Ségond these injuries to the bowel gave rise to serious consequences.

DR. HOWARD A. KELLY of Baltimore, read a paper upon

VAGINAL PUNCTURE AND DRAINAGE FOR THE TREATMENT OF EXTRAUTERINE PREGNANCY RUPTURED IN THE EARLY MONTHS.

At a meeting of the Johns Hopkins Hospital Medical Society, October 23, 1893, he had advocated the treatment of ruptured extrauterine pregnancy by a vaginal opening for the removal of the products, followed by drainage. His first case was operated on October 27, 1892, and was one of the intraligamentary form. An exploratory celiotomy was done, and a mass was found on the right side, 14 x 10 cm. in size, to which the whole omentum was adherent, dragging down the transverse colon; there were also dense adhesions to the small intestines. The uterus lay to the left. The peritoneum at the pelvic brim posteriorly passed directly on to the sac without dipping into the pelvis, but anteriorly and laterally it was lifted up by the sac to such an extent that it was reflected onto the abdominal wall 4 cm. above Poupart's ligament. A complete enucleation of this subperitoneal mass was out of the question, so drainage, extraperitoneally above Poupart's ligament, was determined upon. The colon was set free by tying off the entire omentum from side to side. A free incision was made into the sac above Poupart's ligament and 60 cc. of fluid blood and 240 cc. of clots were removed. The sac was washed out and drained with gauze. There was no marked hemorrhage. The duration of operation was thirty-seven minutes. The patient made a good recovery leaving hospital on thirty-second day.

The next case was operated on February 22, 1893; the third one is reported in the *Johns Hopkins Hospital Bulletin*, for November, 1893. He has had in all thirteen cases treated by vaginal puncture, and drainage with one death not attributable to operation, and without any untoward sequelæ.

Vaginal puncture and drainage is suitable for all cases of extrauterine pregnancy ruptured in the early months, therefore, to the vast majority of cases.

Vaginal puncture and drainage is not suitable: (1) In an unruptured extrauterine pregnancy. (2) advanced extrauterine pregnancy. (3) In a recently ruptured extrauterine pregnancy.

He does not compare the operation with the removal of a dead fetus per vaginam in an advanced extrauterine pregnancy (elytrotomy), nor to cases in which suppuration of the sac has taken place. He reported only one suppurating case, and included that simply to give all his cases treated by the vagina. Method of performing the operation: (1) Careful vaginal and rectal examination to fix exact relation of sac to vaginal vault and rectum. (2) Position of patient, lithotomy posture. (3) Fixing cervix with tenaculum forceps in posterior lip. (4) Opening the sac with scissors. (5) Emptying sac of contents by dilatation of opening, and the careful use of index and middle fingers in removing *debris*. (6) Washing out the sac. (7) Gauze drain fitting loosely.

He leaves the gauze drain in for three or four days, and then gradually withdraws it up to the fifth or seventh day. The sac closes in from two to six weeks, without any marked suppuration.

In four out of the thirteen cases he opened the abdomen before evacuating and draining the sac, by the vagina, in three of them, and above Poupart's ligament in the other. He opened the abdomen in the first two cases, expecting to be able to enucleate the mass in that way, but finding that impossible, he turned to the vaginal route. With his present technic he rarely finds it necessary to open the abdomen at all. He did this, however, in the last case but one, No. 12, because the history of rupture was so negative, that he was doubtful whether he had a ruptured or an unruptured sac to deal with.

Advantages of this operation: The greatest advantage of this method of treatment is, that none of the pelvic structures are removed, while the sac is opened and drained, in accordance with the most recent advances in gynecological technic. A further advantage is, that a serious abdominal operation is avoided and the adhesions walling off the sac are let alone. Several of his patients were so reduced that they could never have survived an abdominal operation.

Dangers of operation: (1) The possibility of a mistake in the diagnosis. (2) Risk of opening the peritoneum. (3) Fatal hemorrhage. (4) Prolonged suppuration of the sac.

Although he made a correct diagnosis in these thirteen cases, he once diagnosed a dermoid cyst as an extrauterine pregnancy, and one a pelvic abscess; he opened and drained both cases, and both recovered. Hemorrhage is the most serious risk incurred; and in one case he had to open the abdomen and extirpate the sac to stop it. The operator, to avoid this accident, ought always be prepared to open the abdomen.

A careful record of his thirteen cases has been prepared by Dr. J. E. Stockes of the Johns Hopkins Hospital, and will appear in the Transactions of the American Gyncological Society.

DR. FERNAND HENROTIN of Chicago, then read a paper upon

TREATMENT OF EARLY RUPTURE OF EXTRA-UTERINE PREGNANCY.

Confining his remarks to a consideration of those cases only in which rupture took place prior to the second month. He divided the cases into classes, viz.: (1) Those in which the rupture is complete, and is associated with free, primary, abdominal hemorrhage; and (2) those in which there is an incomplete rupture into the broad ligament. Prior to the seventh week, the diagnosis of complete primary rupture was that of intra-abdominal hemorrhage. In some of the acute cases it is impossible to remove all the blood from the peritoneal cavity. If there were no evidence of sepsis, only the large clots need be removed, but where sepsis was present, the cleansing of the cavity should be as thorough as was consistent with the condition of the patient. In making the diagnosis, it should be remembered that in free and uninterrupted hemorrhage, the woman remains conscious after the first swoon, and, unlike the fainting woman, her face is constantly blanched. Again, the pains of rupture were more likely to occur in distinct attacks, leaving the patient well in the interval. In tubal abortions, he would expect the pains to recur at short intervals up to the escape of the ovum. If a woman were to suddenly and unexpectedly become faint, and in spite of proper treatment, rapidly pass into collapse, the diagnosis of rupture of an extra-uterine pregnancy and free hemorrhage into the cavity is almost certain. True surgery demanded an immediate ligation of the bleeding point. Such an operation could be performed in a very few minutes, and while it was being done, an assistant might be performing saline infusion. In bad septic cases where the condition of the patient was so bad that there was no time for a thorough cleansing of the cavity, a gauze drain might be inserted.

Dr. H. J. Boldt of New York, said he did not think the treatment advocated by Dr. Kelly in his paper would have many advocates. In one case in which he had performed vaginal puncture, the hemorrhage had been very serious. Nor did he think that many surgeons would agree with Dr. Henrotin that it was proper to operate during shock. He had been interested in the differential diagnosis, as laid down in that paper, but it could hardly be considered as absolute.

Dr. Wathen said he was of the opinion that Dr. Kelly's treatment was the proper one for the special class considered, and he had himself practised it with satisfactory results. He hoped that now Dr. Kelly would become a convert to the vaginal operation for pus cases. In cases in which the hemorrhage and shock were so severe that a laparotomy would jeopardize the patient's life, the surgeon could make an opening in Douglas' pouch.

Dr. Mann said that his experience with the vaginal treatment of these cases had not been so fortunate as Dr. Kelly's. In one case, after having removed the fetus and placenta, there occurred a frightful hemorrhage, which eventually caused the woman's death. The autopsy not only disclosed an enormous sac, which it would have been next to impossible to have effectively packed to control the hemorrhage, but also, on the other side, the remains of another gestation sac, showing how effectually nature had done her work in the first instance.

Dr. Charles P. Noble said that a suppurating hematocele was best dealt with through the vagina, but he would hesitate to resort to this route in any but old cases, on account of the danger of severe hemorrhage. He had operated upon five tubal abortions, and in these, the description of Dr. Henrotin for primary abdominal hemorrhage found its counterpart. A strong argument against the vaginal method was that the ovum might be left in the tube to excite another hemorrhage.

Dr. A. Lapthorn Smith said he was sorry that such a brilliant abdominal surgeon as Dr. Kelly should waste his talents on the vaginal route. Personally, he would be utterly dismayed if required to operate upon a case of extrauterine pregnancy by the vaginal route.

Dr. Baer referred to a case of extrauterine pregnancy, in which a sudden and exceedingly severe hemorrhage occurred. He felt sure that had he been operating on this case through the vagina, the woman must have certainly lost her life before he could have opened the abdomen and controlled the bleeding. He had rarely operated upon patients until they had recovered from shock, and he had never seen a case of extrauterine pregnancy die from the hemorrhage.

Dr. J. E. Janrin said that as long ago as 1867 Dr. Stephen Rodgers of this city, had recommended an exploratory laparotomy in cases of hemorrhage from the uterine adnexa, and Dr. Henrotin's remarks were, therefore, but confirmatory of what had been recommended so many years ago. He had successfully operated in a number of cases in which the hemorrhage was still in progress, but never upon a patient *in extremis*. Having observed a case of fatal hemorrhage from a vessel on the surface of a gestation sac, he had been led to operate, and with success, in several cases in which there were symptoms of hemorrhage, but in which rupture of the tube had not yet occurred.

Dr. S. C. Gordon said that a fairly large experience with this class of cases seemed to justify him in the belief that it was not necessary to operate during collapse. He was not as much afraid of these women dying of hemorrhage as Dr. Henrotin seemed to be.

Dr. Ashton said that the object of operating in these cases was to control the hemorrhage, and as this could be more quickly done by abdominal section, he preferred that method. Moreover, the irrigation of the vagina with hot water was in itself enough to aggravate the hemorrhage.

Dr. Johnstone said that as the danger seemed to increase with each successive attack of collapse, the importance of prompt operative interference in cases giving a history of two or three previous attacks was apparent, General surgeons made it a rule not to operate during shock, if it could be possibly avoided, and the same rule should apply to gynecology.

Dr. Watkins described a number of cases in which he had done the vaginal operation, and laid stress on the fact that in six of them the patient's condition was so bad that it was hardly probable that she would have survived an abdominal operation.

DR. ANDREW F. CURRIER of New York, said that the majority of persons would die if operated upon during shock. If the symptoms present were those of shock and hemorrhage, it was not of much importance whether the diagnosis was ruptured ectopic gestation, or ruptured ovarian cyst.

DR. J. TABOR JOHNSON said that it seemed unsurgical to endeavor to resuscitate a person from shock while the hemorrhage was still in progress, because the measures recommended for establishing reaction from shock were the very ones which would tend to aggravate the hemorrhage. There had been a number of cases reported in which patients had died while the surgeon was waiting for reaction from shock. It seemed to him that the only cases suitable for the vaginal operation were those formerly spoken of under the name of pelvic hematocele.

DR. HENROTIN said that it seemed to him that if there were anything which should not be operated on through the vagina, it was an extrauterine pregnancy. The mistake was sometimes made of making an opening from below simply because a large, boggy mass was felt through Douglas' pouch, but this was a very dangerous procedure, for if there was no limiting sac and bleeding was still in progress, the woman might lose her life from hemorrhage. It was safer in these cases to operate from above. The speaker said that an experience of sixteen years in general surgery had taught him that it was not always necessary or wise to wait for shock to pass off before operating. Of course he would not operate upon a patient already so low as to exhibit that great restlessness so characteristic of approaching dissolution. The shorter the time between the onset of the attack and the occurrence of severe collapse, the more prompt must be the effort made to check the hemorrhage. He was thoroughly convinced that by the method given in the paper, one could, in a large proportion of cases, differentiate between a woman who was simply in a swoon, and one who was in collapse from excessive hemorrhage.

DR. CHARLES P. NOBLE of Philadelphia, read a paper upon

SUSPENCIO UTERI, WITH REFERENCE TO ITS INFLUENCE UPON PREGNANCY AND LABOR.

He said that experience had shown that while this operation was a very satisfactory one from the standpoint of the gynecologist, it was sometimes responsible for difficulty in subsequent pregnancies or labors. He had met with two cases of obstructed labor from this cause, and in one of these it was necessary to perform a Porro operation. This had led him to make a collective investigation, with the following results: (1) That subsequent pregnancies are usually uncomplicated; (2) that uterine inertia is not infrequent; (3) that serious obstruction to labor may result from the fundus of the uterus being imprisoned at the brim of the pelvis. Of 165 pregnancies reported in foreign journals, as occurring after suspensio uteri, there were seventeen abortions, seven premature labors, and sixty labors at full term. Of the latter, there were two artificial extractions, eight forceps deliveries, five versions, and three Cæsarean sections. There were three deaths, or a mortality of five per cent. Although Kelly had performed nearly one-fourth of all these operations done in America, difficult labor had been reported as following this operation in only one instance. The speaker said that he had become impressed with the fact that the real danger in subsequent labors was chiefly from the hypertrophied fundus and anterior wall constituting a tumor, and so blocking the pelvic inlet. To obviate this, he now made the lower angle of the incision stop an inch and a half above the pubis, and passed the sutures through the anterior, instead of through the posterior face of the fundus. Of the other similar operations, Dr. Noble said that it was now generally conceded that Alexander's operation did not interfere with subsequent pregnancy or labor, while vaginal fixation had been responsible for so many operative deliveries, that it could not be considered as a justifiable procedure in women of the child-bearing age.

Discussion of this paper was postponed to the following day.

THIRD DAY—MAY 28TH.

DR. T. A. EMMET said that as he had found that on shortening the round ligaments, Alexander caused at the same time a prolapse of the uterus, he had never felt justified in doing Alexander's operation. Another reason was that he was able to relieve all these cases by plastic surgery.

DR. G. M. EDEBOHLS of New York, said that Alexander's operation had been found to have no deleterious effect on subsequent pregnancies, but vaginal fixation, although still a young operation, had been followed by an appalling list of complicated labors. Ventral fixation occupied an intermediate place. Among his cases of ventral fixation there had been eight subsequent pregnancies, and two deaths, but neither of these two deaths was in any way attributable to the operation. The lower the attachment of the uterus and the more secure the fixation, the better the result from the gynecological standpoint, but the worse in case of subsequent pregnancy. Probably the best way was to attach the uterus squarely by the fundus, and to fasten it to the abdominal wall where it would naturally rest without dragging on the lower attachment.

DR. KELLY said that, being the originator of this operation he had taken a special interest in the collective investigation, and had himself sent out 125 letters of inquiry. By this means he had heard from forty-six married women who had been operated upon by suspension of the uterus. Among these women there had been thirteen pregnancies, with only one difficult labor, and this case was one of his earlier operations, and as a result of sloughing, a very extensive adhesion had formed between the uterus and the abdominal wall. The adhesion here ordinarily consisted only of a long and delicate fibrous band, which suspended instead of fixing the uterus. Such a uterus had all the natural movements, but could not be retroverted. He considered the best technic was that which he had at first recommended, and which he had employed in about 250 operations with satisfaction. Two silk sutures were passed in the peritoneum and through the uterus, just posterior to the

ridge at the top of the fundus. Although he had fixed the uterus low and posteriorly, the fixation had not been firm.

Dr. A. Lapthorn Smith said that he had done the operation according to Dr. Kelly's method fifty times, and the only trouble from subsequent pregnancy had been one abortion at the fifth month. He thought Dr. Kelly's suggestion of taking in less of the abdominal wall would probably avoid further trouble. He had done ventral fixation in cases of extensive disease of the appendages with firm adhesions, and had been surprised to find that many had been relieved entirely of their symptoms by simply the elevation of the ovaries and tubes.

Dr. Ashton said that the statistics regarding the results of suspensio uteri were valueless because of the many different methods that had been employed. The object of the operation should be to suspend the uterus and tilt it somewhat forward, which could only be done by taking advantage of the peritoneal attachment of the new adhesion. In two secondary operations, he had found, by direct inspection, that the adhesions were slender and about two inches in length. He had never been able, as had Dr. Emmet, to cure all these cases by plastic surgery and the use of pessaries.

Dr. Henry D. Fry of Washington, D. C., referred to the case of a woman who had had ventral fixation performed on her when she was about one month pregnant. Pregnancy was not interfered with, and her attending physician had told him that she had been delivered of a living child, weighing 6½ pounds, after a labor of only a few hours. He had recently himself performed ventral fixation on a woman about ten weeks pregnant, because of an incarcerated uterus, yet so far pregnancy had gone on uninterruptedly. Dr. Fry said he thought in considering the statistics of ventral fixation, account should be taken of the length of time that had elapsed after the operation before pregnancy supervened. This factor should exert considerable influence, for naturally there would be less liability to interference with labor if sufficient time had passed to allow of the formation of a slender band of adhesion.

Dr. Noble, in closing the discussion, took exception to the statement of Dr. Edebohls, that the lower and the firmer the attachment of the uterus in the operation of suspensio uteri the better the anatomical and therapeutical result. The very fact that the uterus was fixed, made its condition abnormal. The term "suspension" better described the operation than did "fixation."

Dr. Edward P. Reynolds of Boston, read a paper upon

SOME ASPECTS OF URETERITIS IN WOMEN.

After a brief consideration of the etiology of the disease in general, the writer states that in his experience the majority of cases of ureteritis have been dependent upon an altered condition of the urine, associated with renal insufficiency, and that this paper is confined to a consideration of this class of cases of ureteritis only. The chronic and acute stages of the disease, although essentially the same affection, are treated in separate sections of the paper on account of the marked difference in the clinical pictures which they present.

Chronic Ureteritis.—The characteristic symptomatology of this affection consists in an increased frequency of urination which is increased by the erect posture, but not wholly relieved by recumbency, the necessity of rising during the night for the purpose of micturition being always present in the writer's experience. With this frequency of mictruition is associated a bearing-down pain which is especially aggravated by standing, and relieved by rest in bed. These two symptoms may be due to other pelvic lesions, but should always excite a suspicion of ureteritis. The physical signs of the disease are limited to a complaint of tenderness and usually of a desire to urinate, on compression over the affected end of the ureter or ureters. In addition to this, examination of the bladder usually shows alteration in the appearance of the ureteral orifice, and often in the neighboring mucous membrane of the bladder. In eight consecutive cases of unilateral ureteritis, catheterization of the ureters has shown a decrease of urea from the affected side. The writer thinks it probable that the urine in renal insufficiency may contain irritant substances which are the result of imperfect metabolism and that in unilateral cases, the one-sided ureteritis not improbably bears a resultant relation to the relatively increased renal insufficiency upon that side.

Treatment is divided into palliative and curative methods. The palliative methods are applicable only to cases in which painful micturition is dependent upon ulcerations or localized inflammations of the vesical mucous membrane in the neighborhood of the ureteral orifice. The writer recommends a carefully localized application of the solid nitrate of silver to such inflammatory surfaces. The curative treatment is hygienic and medicinal. It consists of the ingestion of a large amount of water, accompanied by an alkaline diuretic, a bland, nutritious, and largely albuminous diet, restricting the use of most of the more highly flavored vegetables, and absolutely interdicting all strawberries and asparagus. To these measures should be added massage, or light, gentle exercise. The only drugs which the writer has found of value are the so-called alteratives, preferably small doses of mercury, potassium iodid, or mercury and iodid mixed, which act upon the ureteritis, presumably by improving the general metabolism of the body.

Acute Ureteritis.—This is a frequent, though not dangerous affection, which is probably often mistaken for severe intestinal colic, for renal stone, catarrhal appendicitis, or catarrhal salpingitis. It appears as a sudden attack of abdominal pain, which is usually marked upon one side and slight upon the other. It is distinguished from the other affections mentioned by the fact that its tenderness moves steadily downward through the attack, beginning at the pelvis of the kidney and ending in the vesical portion of the ureter. The abdominal tenderness is often easily overlooked on account of its close localization to what the writer calls the three cardinal points in acute ureteritis; the first of which, characteristic of the beginning of the attack, is situated over the kidney and its pelvis; the second, characteristic of the middle portion of

the attack, is identical with McBurney's point, or its fellow upon the other side, *i.e.*, situated half-way between the umbilicus and the anterior superior spine of the ilium; the third is situated about an inch above the middle of Poupart's ligament. Until the time when this last-mentioned tenderness appears, vaginal examination is negative, but at this time, tenderness, and usually swelling of the vesical end of the ureter, can be detected by the finger. The urine is not always characteristic; but occasionally shows crystals of uric acid and calcic oxalate in an otherwise limpid urine.

The affection tends to a recovery; without treatment, it probably ends in the chronic form of the disease, but with treatment similar to that of the chronic affection, is usually completely thrown off.

The paper closes with a report of two typical cases, one of chronic, the other of acute ureteritis, which are quoted as illustrations of the ease with which mistakes in diagnosis can be made.

DR. HERMAN J. BOLDT of New York presented a paper upon

IMPLANTATION OF THE URETER IN THE BLADDER.

He said that among the causes leading to the production of uretero-vaginal fistulæ, the most frequent at the present time is probably vaginal extirpation of the uterus. Formerly difficult parturition was the most prolific source of this malady. It is liable to occur relatively oftener in the hands of experienced operators than in those of less experience, because the former are apt to undertake more difficult cases, especially when operating for cancer. A case of fistula was reported in which he adopted ureterocystotomy. The abdomen was opened and by the guidance of a ureteral catheter the lower segment was safely dissected out of its adhesions. The bladder was now filled about two-thirds full of sterile water to assist in selecting a site for implantation. The bladder was then evacuated, an opening made in the bladder and the ureter drawn through by means of forceps inserted through the urethra. Three fine silk sutures were passed to retain the ureter in place. Recovery was uneventful and the operation a success. The sacrifice of a kidney for the abolishment of a fistula should be a last resort.

DR. MANN thought that the curious difference in the quantity of urea excreted by the two kidneys in cases of ureteritis might be explained by reflex action. It was important to note that the symptoms of ureteritis were due to the irritation of the mucous membrane of the bladder adjacent to the orifice of the inflamed ureter. He had learned from experience that treatment of this vesical mucous membrane by applications of nitrate of silver would relieve the symptoms of ureteritis. Personally, he would hesitate to resort to treatment of the ureter by the use of bougies or irrigations, owing to the great danger of producing traumatism and of causing infection. The majority of cases of ureteritis were certainly chronic, but, as had been stated in the paper, acute cases were sometimes encountered. When these latter were due to lithemia, the true condition was often overlooked, and the pelvic pain attributed to other causes than the true one—the passage of irritating urine through the ureters. He had not had his attention directed before this to the special points of tenderness. Without the employment of measures for improving the general health, *e.g.*, plenty of exercise, and the free use of water internally, it would be difficult, if not impossible, to effect a cure.

DR. E. P. DAVIS said that he had met with certain abnormal conditions of the urine which had proved most obstinate to treatment until he had discovered that they were produced, or kept up by chewing tea-leaves.

DR. A. LAPTHORN SMITH said that ureteritis was a common affection among women, and in his opinion, was a local disease due to an abnormal condition of the urine. Deficient oxygenation would cause the formation of irritating by-products, such as uric acid and oxalic acid. The patient should be made to take sufficient exercise, avoid excessive eating, and drink at least two quarts of water daily.

DR. REYNOLDS, in closing, said that there was a great danger of making false passages by attempts at exploring the ureters by means of rigid instruments.

DR. EDWARD P. DAVIS of Philadelphia read a paper entitled

INTESTINAL BACTERIA AS A SOURCE OF INFECTION COMPLICATING OBSTETRIC OPERATIONS, WITH REPORT OF CASES.

The first case described was that of a young colored girl who had a contracted pelvis, and who was admitted to the Jefferson Maternity so late in pregnancy that the induction of labor was not admissable. The patient's general condition was good, with the exception of obstinate tympany and distention of the upper portion of the abdomen. She came into spontaneous labor after her bowels had been repeatedly moved by laxatives. As the fetus failed to engage in the pelvis, and as the vagina and vulva were small and ill-developed, the patient was delivered by celio-hysterectomy, a living child being born without difficulty. The stump was treated by the intrapelvic method. There was no hemorrhage nor shock. The patient developed, within forty-eight hours, excessive distention of the small intestine, and vomiting. The bowels moved, and the stomach was washed out with but temporary relief. A clinical diagnosis was made of infection by the bacillus coli communis. Efforts to remove the obstruction to the bowel failed, and the patient died. Autopsy showed multiple ulcers of the small intestine, with lymphangitis of the peritoneum and exudate compressing the bowel. Bacteriological examination showed pure growth of the baciilus coli communis, with micrococcus pyogenes albus. Intestinal ulcers were demonstrated by culture examination to have been the point of infection. The incision had healed by first intention, and the stump was healing.

CASE II was that of a Polish woman whose pregnancy was remarkable for profound melancholia and sleeplessness. She had a normal pelvis, and her labor, although tedious and difficult, was successfully terminated by forceps. She bore a large, living child which survives. She had been unusually excitable before labor, and at the time of delivery her temperature was 101, her pulse 120. She speedily developed a high temperature and rapid

pulse, with acute mania. The uterus and genital tract were thoroughly antisepticized without result, Symptoms of puerperal septic infection were absent. The patient endeavored to leap from the window of her room, and attacked one of her nurses. She refused food, and was fed by a stomach tube. Prolonged sponging, bathing, and packing, the use of sedatives, forced feeding and stimulants, had little effect upon her case. She died comatose eleven days after delivery. On *post-mortem* examination, a congenital abnormality of a loop of large intestine in the center of the abdomen was found. This contained masses of partially dissolved feces. The genital tract showed no evidences of infection. These autopsies were made by Dr. Bevan, of the Jefferson Hospital, who has observed in three hundred autopsies at the Philadelphia Hospital eighteen cases of this anomalous loop in the intestine. Fourteen of these patients were insane, or had been at some previous time. Two committed suicide; two were brought into the hospital unconscious, dying of toxemia. In the case reported, the bowels had been thoroughly moved by mercurials and salines. Examination of the blood showed no septic bacteria, but molecular disintegration of corpuscles. A clinical diagnosis of acute puerperal mania was made, while autopsy gave as a cause of the mania chronic toxemia from absorption of bacteria and ptomaines from an abnormal loop of the large intestine.

A colored illustration of the intestinal ulcers in CASE I was exhibited.

DR. R. A. MURRAY recalled two or three cases in which he believed the symptoms of toxemia that were present had been dependent on such an intestinal infection. Such experience emphasized the importance of keeping our patients under observation during pregnancy. In these cases the action of the saline purgatives should be aided by the administration of some "antiseptic cathartic," such as calomel.

DR. GRANDIN said that while he felt sure that he could recall some cases in which, had there been an autopsy held, the same conditions described in the paper would have been found, he felt that a certain danger lurked in this paper, *i.e.*, the danger that many physicians would be content with the diagnosis of intestinal infection when the real condition was puerperal septicemia. The latter diagnosis was disquieting, in that it pointed to his own negligence, or that of some of the other attendants, as the cause. This criticism, of course, did not apply to the cases reported in the paper, for the autopsy was a sufficient confirmation of the correctness of the diagnosis in those particular instances. The lesson to be learned from this very interesting paper was, that the gravid woman should be watched by the physician from the inception of pregnancy to the time of labor.

DR. PHILANDER A. HARRIS of Paterson, N. J., said that he desired to emphasize the fact that modern obstetric teaching had pointed out that very few cases could be accounted for in the way described in the paper.

DR. CUSHING said that the symptoms in the reported cases were such as laparotomists had long recognized as indicative of intestinal infection.

DR. DAVIS in closing the discussion, said that he had presented the paper purely as a clinical study for the thoughtful consideration of expert obstetricians. The clinical picture presented in his cases certainly was not that of ordinary puerperal sepsis. For efficiently cleansing the bowel, it had been recommended to use $\frac{1}{200}$th to $\frac{1}{120}$th of a grain of the bichlorid of mercury internally, several times a day for several days, together with salines.

DR. WILLIAM H. WATHEN of Louisville read a paper upon

TREATMENT OF INTRA-LIGAMENTOUS AND RETRO-PERITONEAL UTERINE FIBRO-MYOMATA.

He said that where the fibroid tumors could be enucleated without excessive hemorrhage, the uterine and ovarian arteries need not be interfered with, but in many cases it was imperative that the uterine arteries should be secured by ligature or clamp before attempting the removal of the tumor or the uterus. He said that in the class of cases specially considered in his paper it would require little more time after the usual preliminary cleansing of the vagina and uterus had been accomplished, to separate the vagina from the cervix, and control the uterine arteries, if possible in continuity near the pelvic wall. The tumor should then be enucleated, and the lower part of the uterus separated from its attachments, after which the abdomen should be opened, and the operation completed from above. Having separated the adhesions, the ovarian arteries are to be ligated close to the pelvic wall, thus cutting off the blood supply to the uterus or tumors. Having next completed the enucleation, the capsule should be sutured in the lower part of he abdominal wound, and the incision closed above.

DR. CUSHING said, that these retroperitoneal tumors usually originated in the cervix, and hence might be below the uterine arteries. He could not see the necessity or desirability of suturing the sac to the abdominal wall.

DR. P. A. HARRIS wished he had known of this method before doing a certain difficult operation a year ago, for he was positive that he could have accomplished it in much less time.

DR. GORDON thought the vagino-abdominal operation often very much easier.

DR. J. TABOR JOHNSON suggested that by continuing the anterior and posterior flaps and making a lateral flap, the dangerous vascular adhesions would be permitted to slip out of the way. The wound could then be closed by a continuous suture. The operation should be suited to the particular kind of tumor.

THE PRESIDENT said that by securing the anterior trunk of the internal iliac, according to the technic of the old operation for aneurism of the internal iliac, one could easily control the blood supply to the field of operation. Experience had shown that there would be an abundant blood supply to the tissues by collateral circulation, notably through the middle hemorrhoidal artery.

DR. HENRY C. COE of New York, presented a paper upon

CÆSAREAN SECTION; SUTURE OF THE UTERUS VERSUS TOTAL EXTIRPATION. (SEE PAGE 601.)

DR. GRANDIN said that where we were dealing with an infected uterus, or one containing fibroids, we were perfectly justified in performing total hysterectomy, but beyond this he could not go. It was not our business to look into the future and ligate the tubes, or take out the uterus because at some future time the woman might become pregnant. Statistics showed that the second Cæsarean section was safer than the first.

DR. GEORGE T. HARRISON of New York, said that it did not seem to him that it was right to remove healthy tubes and ovaries because of possible future complications, but where there was a fair probability that the uterus was infected, it should be removed.

DR. CHARLES P. NOBLE took the same ground as the preceding speakers regarding the ethical question raised, although he would favor extirpation of the uterus if this organ were infected, or if there were so many fibroids present that it did not seem probable that a myomectomy could be performed at some future time.

DR. R. A. MURRAY also took the same ground. We should not, he said, do several operations at once, simply because the abdomen was open.

DR. P. A. HARRIS thought that to remove the uterus simply on the assumption that it had been badly handled before the case came under one's care, was rather too radical.

DR. E. P. DAVIS said that he held it to be the right of a woman who is in a condition where natural delivery is impossible, to demand that further procreation be stopped if this could be done without additional risk. Hysterectomy for this purpose, was a safe operation, and did not interfere with lactation.

DR. H. J. BOLDT said that the last speaker had voiced his own sentiments.

DR. H. J. GARRIGUES of New York denied that a woman had the right to be made sterile, or that the physician's duty was to accede to such a request. He thought that the children had some rights, and that, where a mother was in an advanced stage of tuberculosis for example, the child could be saved from such a maternity.

DR. COE, in closing, said that he had not intended to convey the impression that without the patient's consent he would remove the uterus, just as some years ago many of us had removed ovaries. He did think, however, that in these operations we should look into the future, particularly where the mothers were sickly, and the chances for the children were very poor.

DR. HENRY T. BYFORD of Chicago, read a paper upon

DRAINAGE OF THE STUMP IN ABDOMINAL HYSTERECTOMY.

He described the various methods of drainage that he had adopted in sixty-eight cases. His present method was to sew up the stump with catgut, and drain through an opening in the anterior vaginal wall, just in front of the cervix. Three of his cases had died, and he was convinced that there would have been at least twice as many had drainage been omitted.

DR. G. T. HARRISON remarked that the first person in this country to treat the stump by closing the peritoneum, after a supravaginal myomectomy, was Dr. T. A. Emmet, in 1878. The defect in his technic was the absence of proper drainage.

DR. NOBLE said that after trying various methods, he had come to the conclusion that the careful drainage which Dr. Byford had carefully provided, was unnecessary.

DR. HENRY D. FRY of Washington, D. C., read a paper upon

MYOMECTOMY; FATAL SECONDARY HEMORRHAGE, WITH RISING TEMPERATURE.

He reported a case of myomectomy for fibroids, in which there had been fatal secondary hemorrhage, and the correct diagnosis had not been made because of the steadily rising temperature. The morning after operation the patient's pulse was 76 and her temperature 99° F. The heart action then became rapid and feeble, 140 or 150, and the temperature varied between 100 and 102 or 103°. The symptoms lasted twenty hours, and after death the peritoneal cavity was found to be filled with blood. There was no evidence of infection, and the autopsy showed nothing else to explain the fever.

DR. GRANDIN took the ground that the pulse was a better guide than the temperature, both as to the existence of hemorrhage and sepsis.

DR. J. M. BALDY said that when the temperature became subnormal in these cases of hemorrhage, it was usually too late to help the patient. The pulse was not always a reliable guide, but it was the best we had.

DR. COE also thought the pulse was a fairly good guide to the existence of internal hemorrhage.

DR. A. LAPTHORN SMITH said that a *sudden* increase in the pulse-rate was particularly significant.

DR. BOISE of Grand Rapids said that if after complete recovery from the operation and the anesthetic, the pulse was good, shock could be excluded. If the pulse became more rapid, we must differentiate between sepsis and hemorrhage. In cases of gradual hemorrhage into the peritoneal cavity, the rise of temperature was supposed to be due to the effort of the peritoneum to absorb the blood.

DR. E. P. DAVIS said that the rise of temperature might be explained in this way, or by the occurrence of a slight adhesive peritonitis.

AN ELECTRODE FOR BURNING OFF LIGATURES.

DR. CLEMENT CLEVELAND of New York exhibited an electrode with a platinum loop, which he tied in with his ligature during a vaginal hysterectomy. When it is desired to remove the ligature, the current from a three-cell battery is passed through the electrode, and the ligature liberated. The electrodes being small, light, and flexible, do not interfere with the operation.

DR. J. MONTGOMERY BLADY of Philadelphia read a paper upon

SURGICAL INJURIES OF THE URETER.

He said that uretero-ureteral anastomosis was only applicable to a small proportion of cases, while ureterocystostomy is usually feasible. The danger of immediate obstruction seems to be very great, and secondary obstruction, though possible, had not yet been reported. He

had repeatedly examined two cases with cystoscope since the operation, but had been unable to detect any stenosis of the ureter. Should stenosis follow, it could be more easily detected and treated after uretero-cystostomy. The position of the new opening, high up on the fundus of the bladder, was also a decided advantage, as it protected against infection. If there was a choice between the two operations, the evidence seemed to be in favor of uretero-cystostomy.

Dr. Bache Emmet said that infection of the kidney was liable to occur if cystitis were present, and after either operation he would be afraid of backward pressure and consequent hydronephrosis. It was certainly important to make the anastomosis in a slanting direction.

Dr. Byford thought that from the description of the technic of Kelly's lateral anastomosis, this operation should prove to be the best yet devised.

On motion of Dr. Grandin a vote of thanks was extended to Dr. Henry C. Coe for the efficient services which he has rendered the Society during the six years he has acted as secretary.

The following officers were elected for the ensuing year: *President*, Dr. Chadwick of Boston; *First Vice-president*, Dr. Sutton of Pittsburg; *Second Vice-president*, Dr. Garrigues of New York; *Secretary*, Dr. Goffe of New York; *Treasurer*, Dr. Baldy of Philadelphia.

The Society then adjourned, to meet in Washington, D. C., the last Tuesday in May, 1897.

REVIEWS.

Consumption: Its Nature, Cause, and Prevention, with an Outline of the Principles of Treatment. By Edward Playter, M.D. Toronto: William Briggs. 1895.

Apart from the views which are entertained by the author in favor of the contagion theory of pulmonary consumption, this book is a creditable production. The discovery of the tubercle bacillus led to the almost universal conviction that the etiology of this disease had been forever settled and that its prevention and cure would from this logically and certainly follow. Notwithstanding the fact that there are still many in the profession who, like the author, adhere to this view, numerous events have transpired since then which unmistakably show the fallacy of this position, and in consequence there is growing evidence that professional opinion is rebounding from the extreme ground which it at first assumed. Among the most encouraging signs of this reaction is the fact that there is neither in England nor in Germany an author of any great note or reputation, who has written a special work on pulmonary consumption during the last decade, who fully indorses the contagion theory of the origin of pulmonary consumption. A list of these authors includes the names of Theodore Williams, Douglas Powell, and Wilson Fox, of England; Alexander James, of Scotland, and Brehmer, Dettweiler, and Aufrecht, of Germany. Recent information also indicates that Jaccoud, the eminent French writer on this subject, has revised his earlier views on this subject in the same direction.

The other causes and concomitant conditions of pulmonary consumption which are treated of here are, the lowering of the general health, want of apex expansion, diminished chest capacity (so beautifully brought out by the author's own collective investigation), defective pulmonary innervation, overheated air, heredity, want of sunlight, neglected "cold," dampness, imperfect food supply, and injurious occupations.

As measures of prevention, the author discusses in a very instructive and interesting manner the importance of promoting general health and vigor, of pure air and sunlight, nourishing food, general bathing, comfortable clothing, requisite amount of exercise, avoidance of overwork and excesses of all kinds, sound sleep, general and pulmonary gymnastics, use of cold baths, watchfulness of children who are predisposed to the disease, prevention of infection, and climatic changes. This is by far the most valuable part of this work and its teachings cannot be taken to heart too seriously.

An American Text-book of Obstetrics for Practitioners and Students. By James C. Cameron, M.D., Edward P. Davis, M.D., Robert L. Dickinson, M.D., Charles W. Earle, M.D., James H. Etheridge, M.D., Henry J. Garrigues, M.D., Barton Cooke Hirst, M.D., Charles Jewett, M.D., Howard A. Kelly, M.D., Richard C. Norris, M.D., Chauncey D. Palmer, M.D., Theophilus Parvin, M.D., George A. Piersol, M.D., Edward Reynolds, M.D., Henry Schwarz, M.D. Richard C. Norris, M.D., Editor; Robert L. Dickinson, M.D., Art Editor. With nearly 900 colored and half-tone illustrations. Philadelphia, 1895: W. B. Saunders.

A glance at the galaxy of prominent authors, who have contributed to this work, naturally leads one to expect a valuable literary achievement; but no matter how critically a judge reviews this book, we doubt not that his expectation will be more than realized.

We have rarely seen a book representing the efforts of several writers having a more homogenous character, and after a most critical review, we are forced to the conclusion that this book equals, if not surpasses, any work of a similar character published in this country or in Europe.

As space forbids a detailed review, we desire, before discussing the literary part, to compliment the editor and his able associate, Dr. Dickinson, on the high artistic merit of the work. The book contains about nine hundred artistic illustrations, many of which are original. For the first time, we believe, the successful attempt has been made to carry out systematically the principle to draw all figures to a uniform scale, usually one-third to one-sixth life size.

Parts I. and II. contain the anatomy of the pelvis, the anatomy and physiology of the female generative organs, and the development and physiology of the fetus, all by Piersol. We know that this most important subject is usually passed by the average student as tiresome and

difficult. We are pleased, therefore, to note that he has succeeded in presenting this part in an interesting and, at the same time, thoroughly scientific manner.

The diagnosis, hygiene, and the management of pregnancy are jointly by Palmer and Piersol, while Davis, Etheridge, and Kelly are the contributors to the chapter on the pathology of pregnancy. We wish not to detract from the merit of the other writers if we emphasize the excellence of the chapter on extrauterine pregnancy by Howard Kelly.

The chapter on the physiology of labor, by Dickinson, is well written and beautifully illustrated, while the description of the management of labor, by Jewett, has rarely been equaled, and never excelled. Jewett is the first American author who has given to abdominal palpation the important position which this subject deserves. The mechanism of labor is exhaustively treated by Reynolds, and while not agreeing with him in all points, we do not hesitate to approve of its general excellence. We regret that space forbids more than a passing note to the magnificent contribution of Hirst on the subject of dystocia due to anomalies in the forces of labor. The chapter by Parvin and Schwartz on dystocia, due to accidents and diseases, contains the latest views, and is thoroughly up-to-date. The same can be said of Jewett's contribution to the physiology, diagnosis, and management of the puerperium.

The pathology of the puerperium is by Schwarz, Norris, and Garrigues. In this chapter we wish to mention the magnificent illustrations depicting lacerations of, and the methods for repair of, the perineum, Garrigues has handled the subject of puerperal fever or infection in a masterly way, yet we regret that we find statements in this chapter which are not harmonious with our present knowledge of puerperal fever. We cannot agree with the statements of Garriguez that puerperal fever is communicated by the air, or that a dead rat in the cellar can be the source of infection. If this were true, what would become of the women confined in tenement-houses, which houses are notorious for their bad plumbing, and where occlusive vaginal dressings are rarely obtainable? Yet reports from trustworthy sources prove that women can be delivered in these houses with nearly the same safety as in well-kept maternity hospitals. No, puerperal fever is not communicated through the air, nor does the woman generate the poison in her body; dirty hands and instruments are the sole sources of infection. The prophylaxis, therefore, is clear and simple.

The description of the physiology and pathology of the newborn infant, by Etheridge and Earle, is brief, but lucid. Cameron and Dickinson are the authors of the part on operative surgery, except the chapter on symphyseotomy, which is by Jewett. We have only praise for this part of the book.

The work ends with a chapter by Hirst on celiotomy for puerperal sepsis. This subject is yet in the stage of development, but we doubt if the operation will ever become popular.

In conclusion, we again wish to compliment the editor, his collaborators, and also the publisher, on the excellence of their work. Americans may feel justly proud to call such a text-book of obstetrics their own.

A Text-book of Practical Medicine. By Alfred L. Loomis, M.D., LL.D., Professor of Pathology and Practical Medicine in the Medical Department of the University of the City of New York; Visiting Physician to Bellevue Hospital, etc. Revised and enlarged, with two hundred and seven illustrations and one chromo-lithographic plate. Eleventh edition; 1134 pages.

The present edition of Dr. Alfred L. Loomis' Text-book was partially revised at the time his fatal illness overtook him. Dr. Loomis' reputation as a teacher of medicine and the place won by his work, which has passed through ten previous editions, make extended comment unnecessary. The Text-book has always been a brilliant exposition of the practice of medicine, particularly from the standpoint of American observation, and this last edition has been revised satisfactorily. The departments of Rhinology and Laryngology and Neurology were revised at Dr. Loomis's request by Drs. Coakley and Fisher. Criticism might be offered to some parts of the work and it might be questioned whether positions taken by the author have not been disapproved; but on the whole Dr. Loomis's book still remains standard.

ANNOUNCEMENT.

THE SECOND PAN-AMERICAN MEDICAL CONGRESS.

The Congress will meet in the City of Mexico on the 16th, 17th, 18th, and 19th of November, 1896.

ENROLLMENT.

Article 1. In order to be properly enrolled, each member of the Congress will pay to the Treasurer thereof in the City of Mexico, the sum of five dollars gold.

GENERAL SESSIONS.

Art. 2. There will be one opening session, one closing, and one intermediate session of a purely scientific character.

Art. 3. The opening session, which will be of a solemn character and presided over by the Supreme authority of the Nation, besides being attended by the members of the Congress, will also be attended by the members of scientific societies, and other distinguished persons who may be invited. The session will be opened with the report of the General Secretary.

This will be followed by a speech of welcome, pronounced by the President of the Congress.

Two members will then speak on scientific subjects, and they will be followed by a speech from the President of the Republic. It is strongly recommended that the scientific speeches should be of short duration.

The intervals between the speeches will be filled up with musical performances.

Art. 4. At the closing session the General Secretary will notify the place designated by the Congress for holding the third meeting.

ART. 5. The Treasurer will present his accounts to the Congress, showing the disbursements made of the funds entrusted to his care.

ART. 6. A scientific speech will be delivered and a short speech by one Representative of each one of the nations attending the Congress.

ART. 7. In the intermediate session four speeches will be delivered on general matters by persons who are highly distinguished in medical science, and who, having been in due time invited to do so, have accepted the commission; one of these speeches being pronounced by a Mexican physician who shall be invited to do so by the Committee of Management.

ART. 8. No discussion will be held in the General Sessions.

SESSIONS OF THE SECTIONS.

ART. 9. These sessions will be held from 9 to 12 A.M. and from 3 to 5 P.M. in the places that may be designated by the Organizing Committee. They shall be presided over by the President of each section, alternating with the Vice-Presidents of each one of the nations that are represented in the respective sections.

ART. 10. The person who may be appointed by the Committee of Organization will be the ex-officio Secretary of each section, and he will fill his post alternately with the Secretaries of the nations who may be represented in the sections; but should the latter not be present their places will be supplied by the President in office.

ART. 11. The President will direct the discussion in accordance with the order of the day and will decide all questions that may arise and that may not be provided for in these regulations.

ART. 12. The ex-officio Secretary will make out the minutes, and for that purpose, besides his own notes, will collect those of the Secretaries who may have acted in the section. He will also collect from the persons who may have spoken the written extracts referred to in Article 19.

ART. 13. All questions relating to the debates which are not provided for in these Regulations will be decided in accordance with general parliamentary practice.

ART. 14. The voting will be by name or by putting the question.

PAPERS, EXTRACTS THEREOF AND DISCUSSIONS IN THE SESSIONS OF THE SECTIONS.

ART. 15. All papers will be presented in writing.

ART. 16. Each author will forward to the Secretary of the Organizing Committee in the City of Mexico and before the first day of August of the present year an extract not exceeding three hundred words of the paper to be presented by him. These extracts will be printed in English, French, and Spanish and will be distributed to the members of the Congress before the session in which they are to be read.

ART. 17. No paper will be announced which is not accompanied by this extract; but the authors who comply with these conditions will have a right to have their work published intact in the Transactions of the Congress.

ART. 18. The reading of the papers in the sessions must not last more than twenty minutes; when the papers are so long that they cannot be read within that time the authors will give extracts from them, either in writing or by speech; but they will be published intact in the Transactions of the Congress and in the language in which they have been written.

ART. 19. The extracts referred to in the preceding article will be delivered at the same time as the papers to the Secretary of the Section to which they pertain.

ART. 20. The members of the Congress who may take part in the discussion in any section will present their speeches in writing at the termination of the sessions to the respective Secretaries of such sections, and they will also be published in the Transactions.

ART. 21. The papers which have been announced for reading in the order of the day in each section will serve as subjects for discussion. In such discussions no speaker will be allowed to speak more than once and for five minutes; but the author of the paper under discussions will be allowed a reply which will not exceed ten minutes.

AUXILIARY COMMITTEES IN THE MEXICAN REPUBLIC.

ART. 22. These committees will be appointed by the Committee of Organization and will be composed of one member for each Local Medical Society, or in their absence, of one physician for every center of population. They will cooperate with the Committee of Organization in promoting the success of the Congress. Said Committees will be appointed during the first months of the present year.

EXECUTIVE COMMITTEE.

ART. 23. In order to form this Committee the Organizing Committee will appoint seven members, including the President, Secretary, Treasurer, and the Mexican representative in the International Executive Committee, and such members will attend to everything relating to the business of the Congress in accordance with the regulations that they may adopt for that purpose.

DR. MANUEL CARMONA Y VALLE,
DR. RAFAEL LAVISTA,

Mexico, January, 1896.

CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MAY 16, 1896.

May 14th.—Medical Inspector R. A. MARMION ordered as member of the Board of Inspection and Survey, June 3d, and member of Medical Board, Navy Yard, Washington, D. C.

Medical Director W. K. VAN REYPEN, granted three months' leave of absence from June 3d, with permission to leave the United States.

FOR THE WEEK ENDING MAY 23, 1896.

Assistant Surgeon H. D. WILSON ordered to examination preliminary to promotion.

Assistant Surgeon C. M. DE VALIN detached from the Philadelphia Hospital and ordered to Hospital Chelsea.

Assistant Surgeon E. M. SHIPP detached from the U. S. R. S. "Vermont" to the U. S. S. "Monongahela."

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXVIII. NEW YORK, SATURDAY, JUNE 20, 1896. NO. 25.

THE DIPHTHERIA ANTITOXIN QUESTION--DISCUSSION BEFORE THE NEW YORK ACADEMY OF MEDICINE.

ORIGINAL ARTICLES.

CLINICAL OBSERVATIONS UPON THE USE OF ANTITOXIN IN DIPHTHERIA; AND A REPORT OF A PERSONAL INVESTIGATION OF THIS TREATMENT IN THE PRINCIPAL FEVER HOSPITALS OF EUROPE DURING THE SUMMER OF 1895.[1]

BY JOSEPH E. WINTERS, M.D.,
OF NEW YORK.

SINCE Behring's treatment for diphtheria was proclaimed to the medical profession by Roux at the Budapest Congress in 1894, sufficient time has elapsed to warrant our taking a careful analytical review as to what has transpired with reference to it. Behring's antitoxin was given to the world as a specific against the toxins of the diphtheria bacillus. It has no action on the bacillus; this is not destroyed by the antitoxin; it is not rendered less virulent; it is no way influenced by the treatment. Behring has told us that his remedy has no influence on the poisons of other bacilli. Diphtheria in man scarcely ever occurs from a pure infection by the Loeffler bacillus. Almost invariably we find in addition to the specific diphtheria bacillus, streptococci, staphylococci, etc. The poisonous substances of the latter bacilli are in no way influenced by antitoxin. This fact limits very much the application of Behring's treatment to diphtheria in man. The toxin of Loeffler's microbe causes the cardiac paralysis, the albuminuria, and the paralytic phenomena. These were to be prevented by the neutralizing effect of antitoxin. If antitoxin is an antidote to the toxin of the Loeffler microbe, cardiac depression, death from cardiac paralysis, albuminuria and post-diphtheritic paralysis should all be prevented by the action of this agent. It was to remedy these manifestations of the disease that Behring gave to the world his antitoxin. Behring told us his treatment to be effective must be applied early in the disease. To get the maximum effect toxin and antitoxin must be applied at the same moment and at the same spot.

Armand Ruffer states that if you inject toxin on one side of the body, and antitoxin on the other side at the same time fourteen times as much is required to protect the animal; if there is a delay of one hour, one hundred times as much is required to protect the animal, and if there is a delay of eleven hours, five thousand times as much is required to protect the animal. In diphtheria in man we can never apply the antitoxin at the site of infection, nor at the moment of infection. A period necessarily intervenes from the time of infection until there are sufficient symptoms to call attention to the illness; and as the result of this there is a great limitation to the application of Behring's remedy to diphtheria in man. Another consideration of prime importance is, if we are to attribute the reported decrease of mortality of diphtheria to the action of a specific, this decrease must be uniform and constant. There must be the same reduction in mortality in all parts of the world where the remedy is applied. For instance, a mortality of eight per cent. in Paris and twenty-eight per cent. in London does not mean that the low mortality in the former city is due to the treatment, but that it is due to a difference in the character of the epidemic, and that when Paris is visited by an epidemic of the same severity as the one that exists in London it will have the same mortality in spite of the treatment. Again, if there is at work but a single factor, viz., antitoxin, in the reduction of mortality, that reduction must be below the lowest mortality recorded in the natural history of the disease in any part of the world, and it must be steadily maintained below this rate in all parts of the world; otherwise, the variations in mortality may be said to be due to the epidemic character of the disease.

We find recorded the following divergencies in the deaths from diphtheria, owing to the differences in the type of the disease:

[1] Read before the New York Academy of Medicine, May 21, 1896. Abstract made by the author especially for the MEDICAL NEWS.

In New York in	1884	1090
" " " "	1887	2167
In Boston in	1891	232
" " "	1894	817
In Philada. in	1888	350
" " "	1889	375
" " "	1892	1425

The rule of uniformity of results applies to reports by individual observers. If one hundred physicians report five thousand cases of diphtheria, treated with antitoxin, with a mortality of five per cent, and ten physicians report five hundred cases, treated with antitoxin, with a mortality of fifty per cent., the only logical conclusion is that there was a difference in the character of the cases in the two series, and that when the one hundred physicians meet, with a series of cases of the same type, as those treated by the ten physicians, they, too, will have a mortality of fifty per cent.

The most misleading part of the antitoxin literature is the constantly quoted percentage of mortality. For instance, the mortality from diphtheria in the City of Boston in 1895 was 14.48 per cent.; in 1893, 32.49 per cent.; and yet there were 112 more deaths from diphtheria in the City of Boston in 1895 than there were in 1893. The percentage mortality from diphtheria in the Boston City Hospital in 1893 was 48.44 per cent., and in 1895, 13.21 per cent.—and yet we find that there were 203 deaths from diphtheria in the Boston City Hospital in 1893 and 207 deaths in 1895.

BOSTON CITY HOSPITAL.

Year.	Cases.	Deaths.	Per cent.
1893	419	203	48.44
1894	598	266	44.48
1895 (antitoxin)	1566	207	13.21

From the foregoing it is readily seen that the percentage mortality is not only misleading, but is absolutely worthless unless accompanied by the actual number of cases reported and the actual number of deaths; and the report must also include a series of years in order to enable the reader to compare present results with the results in previous years when there was a mild type of the disease. Reports on the antitoxin treatment having ingeniously compared the years of highest mortality instead of including all years.

At the beginning of the antitoxin treatment Behring told us that all cases treated on the first day of the disease could be saved; of those coming under treatment on the second day, nearly all, and of those brought under treatment on the third day, the larger part of them. Behring's words were, "We have it in our hands to reduce the mortality from diphtheria to one-tenth of its former rate. Let us see how this promise of Behring's has been verified.

At the Willard Parker Hospital during the first nine months of 1895, the results were as follows:

	Cases.	Mortality. Per cent.
First day	108	10.09
Second day	130	25.19
Third day	116	34.18

A few cases may be cited showing actual results when treatment is begun in the earlier part of the disease:

Case I.—Six years old, admitted to scarlet fever ward February 1, 1896; recovered from scarlet fever and was ready for discharge. March 19th, at 11.30 A.M. she complained of sore throat. The diagnosis of diphtheria having been made by bacteriological examination, she was injected with two thousand units of antitoxin—just forty hours after the disease began. In spite of antitoxin, croupy symptoms, which manifested themselves early, increased, and intubation was done at 10 A.M., 46½ hours after the beginning of her illness. On the evening of the same day intubation not affording sufficient relief from the stenosis, tracheotomy was performed. Child died at 9.45 P.M.

In this case we have an instance of a child developing diphtheria in the hospital, being put upon serum treatment as soon as the diagnosis was confirmed. Notwithstanding this, the local process extended, even intubation not affording sufficient relief.

Case II.—Aged two and one-half years, admitted April 22d, ill one-half day. Throat clear, tonsils red and somewhat swollen, croup, some retraction, no cyanosis. Under the head of clinical notes we find, "Child rather croupy on admission." Antitoxin 2000 units on admission. Patient admitted 22d April about midday. April 23d, 8.55 A.M., intubation became necessary; 2000 more antitoxin units; temperature on admission, 100.8; April 23d, temperature 103.2; April 27th, temperature 99; April 28th, temperature 105; April 30th, temperature 101.6; afternoon of same day, 105.2. May 10th, baby died at 2.25 A.M.

This is an extraordinary record. Child had been ill one-half day on admission. Clinical notes state "Child rather croupy on admission." About the only evidence of disease then was, as stated above—in spite of antitoxin 2000 units, croup increased during the night; intubation became necessary the following day, about twenty-one hours after admission. Next, observe the

common temperature range which occurs when the patient shows unusual susceptibility to antitoxin.

CASE III.—Aged two years, admitted October 22d, one day sick. Marked injection and swelling, dirty white membrane on left tonsil, croup. Prognosis doubtful. Antitoxin 2000 units on admission. Admitted 9.30 A.M., intubated 4.15 P.M. October 23d, antitoxin 2000 units; 9.45 A.M., tube coughed up; 10.05 A.M., intubated, temperature 2 P.M. 104.6, hypodermic of brandy and nitro-glycerin, hot bath, etc.; October 24th, antitoxin 1200 units, 11.45 A.M., temperature 104, sponging, etc.; October 27th, temperature 105, sponge baths nearly every hour; October 28th, rash; October 29th, tube removed; November 1st, temperature went to 105, sponging almost hourly; November 3d, temperature 105.8, sponge baths nearly every hour; November 5th, 102 to 105; November 6th, temperature 105.8, sponge baths constantly kept up; November 7th, temperature 101.2 to 106.2, sponge baths almost constantly; November 8th, temperature 102 to 106; November 9th, patient died at 6.40 P.M.

Here we have a baby two years old, sick one day when admitted to the Hospital, October 22d, 9.30 A.M., given antitoxin immediately (in all 5200 units), and the result is shown by the clinical history. If antitoxin has any possible effect in neutralizing the poison of diphtheria, in relieving or preventing stenosis, or in any way allaying laryngeal symptoms, only a very small part of the clinical history here recorded would have manifested itself. There are several histories which show undoubted instances of the bad effects of antitoxin on nervous centers.

CASE IV.—Child aged fourteen months, admitted November 6th, illness began November 3d. Small patch of membrane on right tonsil, K.-L.B., no complication. Antitoxin 1000 units on admission. November 9th, slept at intervals quietly, but was very restless when awake; November 10th, extremely restless most of the night, temperature 104, sponge bath; November 12th, pulse very weak; November 20th, rash appeared; November 6th, antitoxin 2000 units, 5.30 A.M., intubated at 1 P.M., very restless during the day, 8.15 P.M. temperature 106. Child failed to respond to stimulants. Temperature became more and more elevated, in spite of sponge bath. December 7th, died at 12.30 A.M.

According to the record, this child had almost no illness on admission. It became very restless after the first injection of 1000 units of antitoxin. Restlessness reappeared in exaggerated form after injection of antitoxin of 2000 units, along with high temperature and rapid respiration, until death.

CASE V.—Child, aged seven months, admitted February 4th, three days sick. Nothing in throat. Slight laryngeal symptoms. Clinical note states: "Slight croup, otherwise good condition." February 5th, antitoxin 2000 units; February 6th, antitoxin 2000 units; 4 A.M. temperature 104.2; February 11th, temperature suddenly rose and erythema appeared in patches over the body; temperature in the evening reached 105.4. February 12th, rash more marked since midnight; marked opisthotonos and stiff neck. February 12th, temperature 106 all night. February 14th, glands and right side of neck swollen, temperature 104 to 106, until March 18th, patient had convulsions during the night. March 19th, child died 9 P.M.

CASE VI.—Child aged one year, admitted October 13th, three days sick, marked swelling and injection, no membrane, croup; intubated on admission. October 13th, antitoxin 2000 units. October 14th, antitoxin 2000 units. October 14th, tube coughed up at 4.10 A.M.; had to be reintubated at 8.30 A.M. October 15th, tube coughed up at 10.30 A.M.; reintubated 12.30 P.M. October 16th, tube coughed up at 7.10 A.M. October 19th, temperature suddenly rose to 104; temperature remained high, but somewhat fluctuating, until 21st, when it reached 105.4, and the baby had slight convulsions. In the afternoon, respiration became very superficial; patient failed to respond to stimulants. October 21st, died at 5.25 P.M.

CASE VII.—Child, aged fourteen months, admitted February 20th, five days sick. Rather thick patch on right tonsil, cry and breathing croupy, no retraction. "Patient admitted in croupy condition; not bad enough to require intubation: prognosis good." Antitoxin 2000 units. February 21st, antitoxin 2000 units at 10.15 A.M. Intubated at 2.10 P.M. 5.45 P.M., tube removed. February 23d, 8.30 A.M., temperature 104.5° F.; 12 M. 105° F.; pulse, 184; respiration, 84. 11 P.M., temperature, 106.2° F.; opisthotonos; plunge bath for ten minutes. February 23d, temperature down, but still opisthotonos and great prostration. February 29th, opisthotonos; eyes rolled up, with lids half closed when asleep. March 3d, opisthotonos and rolled up eyes. March 6th, died at 8.15 P.M.

CASE VIII.—Child, aged three years, admitted February 17th. Four days sick. Much membrane on either tonsil, and in pillars of fauces. Nose plugged; prognosis doubtful. Antitoxin 2000 units on admission. February 18th, antitoxin 2000 units. February 19th, antitoxin 2000 units. February 21st, patient seems better today. This evening he gave a peculiar cry, heard by the nurse, and was dead on the arrival of the physician a moment later. There were no heart-sounds, but artificial respiration was kept up for ten minutes, and stimulants were also given. Patient gasped several times and died.

CASE IX.—Patient, aged sixteen years, admitted May 20th; illness began May 18th; well-devel-

oped and nourished. Glands of the neck enormously swollen; throat much congested; swelling and implication of left tonsil, right tonsil, and right peritonsillar space, and whole area back into pharynx covered with a dirty white deposit. Nares partially obstructed; prognosis favorable. Antitoxin 10 cc. $\frac{1}{1000}$ injected on admission. May 31st, 9 cc. $\frac{1}{1000}$. May 25th, 7 cc. $\frac{1}{1500}$. May 26th, pulse 26 to 30 per minute. Patient died at 10.30 P.M.

This was a remarkably large, strong, well-developed young lady, who was brought to the Hospital as soon as the diagnosis of diphtheria was made. If antitoxin has any specific influence over the toxin of diphtheria this patient should have been saved. As the report of the hospital shows she died from the effects of the toxins on the heart and nervous centers. The pulse having ranged during the last twenty-four hours of life from 26 to 30 per minute, even with the foot of the bed elevated, and with the use of all possible stimulants.

These histories are of cases brought under treatment in the early part of the disease—many of them on the first and second day. They had full doses of a supposed specific, and we do not find recorded in the clinical history one statement which would indicate that this specific modified in any particular a single manifestation of the disease, either in the laryngeal or non-laryngeal cases. Not one item in the clinical records can be found to indicate that any one of these cases was in any way benefited by the antitoxin. This is particularly noticeable in the laryngeal cases. Patients brought in without evidence of very marked croup, and after receiving full doses of antitoxin, had to be intubated twelve and twenty-four hours after hypodermic use of this so-called specific. The clinical records of these cases are totally against the use of antitoxin in the treatment of diphtheria. A careful study of these records will, it seems to me, convince one who is familiar with diphtheria that there are clinical features here recorded which are due to the treatment and not to the disease. These features are referable to the kidneys, nervous centers, temperature, and respiratory organs. There are forty-one similar cases reported. The numerous cases quoted from journal literature, showing the injurious effects of antitoxin, are many of them exact counterparts in their clinical course of the Willard Parker Hospital cases here reported, and taken together, are confirmatory of the view that antitoxin may prove an immediate fatal poison, even when given in immunizing doses—that it may cause nervous phenomena, convulsions, etc., that it may cause anuria, nephritis, albuminuria, hematuria, cardiac collapse, high and uncontrollable temperature, probably due to septic processes, septic pneumonia, subcutaneous hemorrhages, petechiæ, arthralgia, joint effusions, intestinal hemorrhages, fetid diarrhea, etc.

In New York and elsewhere it has been claimed in defense of the serum that the unfortunate ill-effects, in the form of high fever and suppurations, are due to streptococcus infection; but if this were really the case they should supervene while the morbid affection is in process of evolution in the throat; whereas, they usually supervene after the disappearance of all throat lesions. It is now stated that the bad effects, which formerly resulted from the use of antitoxin, were due to the amount of serum injected, and that with the use of a more concentrated serum there would be less pneumonia and bad after effects than formerly. This is a very weak admission. It is an admission that there are bad effects from the serum. One year ago it was asserted most positively by the advocates of this treatment that there was no bad effects—that it was absolutely harmless in doses of any amount.

ANTITOXIN IN PRIVATE PRACTICE.

Dr. Edwin B. Tefft (New Rochelle) reports five cases of diphtheria, treated with antitoxin, three deaths, mortality sixty per cent. During the same period there were five cases stated by Dr. Tefft to be equally severe, treated without antitoxin, all recovered. Cases treated with antitoxin had the same internal and local treatment as those treated without antitoxin. These antitoxin cases had a so-called specific at the very beginning of the disease, and in addition such tonic, stimulating and local antiseptic treatment as one of our best physicians could devise, and yet they show a mortality of sixty per cent., as contrasted with no deaths in five other cases treated without antitoxin.

Dr. de Kraft had three cases of diphtheria in one family, two treated with antitoxin at the beginning of the disease and both died; one without antitoxin got well. Another patient in Dr. de Kraft's practice died one hour after the injection of antitoxin.

Dr. J. C. Shannon recently treated two patients in one family with antitoxin at the very outset of the disease, and both died.

Dr. Koempel reports case of a child taken ill on the night of April 22d. Antitoxin during the first twelve hours; second dose the following day. Child died twenty-four hours later.

Dr. J. H. Bache reports three patients treated at the beginning of the disease, two of whom died. A third case, the child of a physician, barely escaped death from the after-effects of antitoxin.

Dr. P. H. Ernst reports twelve patients treated with antitoxin, 7 deaths, mortality 58.3 per cent.; 65 patients treated without antitoxin, 11 deaths, mortality 16.9 per cent.

Dr. John Dorning employed antitoxin in his private practice in seven consecutive cases of diphtheria, in the early part of the disease, in some of the patients during the first twelve and eighteen hours, and all the patients died.

MORTALITY IN THE WILLARD PARKER HOSPITAL.

Year.	Cases.	Deaths.	Per cent.
1894 (non-antitoxin)	699	205	29.32
1895 (antitoxin)	778	190	24.42

Could those cases be eliminated which gave no clinical evidence of diphtheria, the mortality of twenty-four per cent. for 1895 would be greatly increased.

Dr. Ewing made an investigation in the Willard Parker Hospital, with reference to influence of antitoxin on the blood. His investigations included 53 patients with diphtheria, 50 of these were injected with antitoxin, 19 died, mortality H. 38 per cent. Dr. Ewing's investigations in the Hospital was in cases in which there was clinical evidence of diphtheria; and my impression is that this report (38 per cent. mortality) would fairly well represent the actual mortality of the Willard Parker Hospital at the present time under serum-therapy, if patients who have clinical evidence of diphtheria were subjected to this treatment to the exclusion and elimination of those cases which have no clinical data to warrant the diagnosis of diphtheria. In order to determine the result with reference to larger or smaller doses of serum, it was decided in the autumn of 1895, to give to alternate cases as admitted into the hospital, doses of serum of 1000, 2000, and 3000 units, respectively. There were two series of cases, known as mild and severe, having 2000 and 3000 units respectively. In the two series of cases marked "severe," having 2000 and 3000 units respectively, at a dose, there were 23 patients in the series having 2000 units, of whom 7 died, mortality 30.4 per cent.; and there were 22 cases in the series marked "severe" having 3000 units; of these, 11 died, mortality 50 per cent. In the 2 series marked severe, the cases were probably of nearly equal severity, inasmuch as they were alternate cases as received into the Hospital, the mortality being higher with the larger doses of serum, in a series of parallel cases. Since these experiments, no child has received doses of 3000 units. In this series of experimental dosage, there were 94 cases, 24 deaths, mortality 25.5 per cent. Children under two years in 1894, 163 cases, 84 deaths, mortality 51.5 per cent.; in 1895 (antitoxin year), 153 cases, 95 deaths, mortality 62.1 per cent.

At the very time of life when diphtheria is most dangerous, we have in the Willard Parker Hospital a mortality of 10.6 per cent. greater with antitoxin treatment than without.

ANTITOXIN IN NEW YORK FOUNDLING ASYLUM.

Professor J. Lewis Smith has reported 31 diphtheria patients treated with antitoxin in the New York Foundling Asylum, 12 on the first day, 17 on the second or third days, 2 on the fourth or fifth days; 17 died, mortality 54.8 per cent. Mortality in New York Foundling Hospital in 1894 (non-antitoxin year), 24 per cent.; 1895 (antitoxin year), 45.7 per cent.

MUNICIPAL HOSPITAL, PHILADELPHIA.

During the year 1895, there were 706 cases of diphtheria treated in the Municipal Hospital, Philadelphia; 302 of these received serum; 404 treated without serum. No patient was injected who had been ill more than four days at the time of admission to the hospital. Cases that were considered hopeless on admission did not receive serum treatment; all patients that were considered hopeless and brought to the hospital were placed with the non-serum treated cases, and some of these died within an hour after admission. The mortality in the 302 cases treated with serum was 28.1 per cent. The mortality in the 404 cases treated without antitoxin was 25.9 per cent. The cases treated with serum had the same local antiseptic treatment and the same internal medication and stimulation that were given to the series of non-serum treated, and yet with a so-called specific added to the treatment in a far more favorable series of cases, there is a higher death-rate than in those not treated with serum.

RESULTS IN BLEGDAM HOSPITAL, COPENHAGEN.

Fifty-one cases of severe diphtheria, treated with serum, 46 cases of severe diphtheria treated without serum, during the same period, mortality 33 per cent. in both series. The average age of those treated without serum was lower than those treated with serum. Among those who died, those who were treated with serum, were admitted

earlier to the Hospital than those who were not so treated. At the time of admission to Hospital, complications were more pronounced in the cases treated without serum, the air-passages being affected in 8 cases, while with those treated with serum, only 3 were affected. Severe complications of the kidneys (after admission to the Hospital) were observed only in those treated with serum. The serum was used earlier in the fatal cases than in the cases which recovered. That is, the day of the first injection was, on an average, earlier in the fatal cases than in the successful cases. From our experiments we cannot see any favorable action of the serum. On the other hand, we observe more severe hemorrhages, albuminuria, nephritis, toxic-anuria, fever, eruptions, etc., in those treated with serum. The serum was also used in croup cases complicated by severe diphtheria, and in mild cases of croup for the purpose of preventing stenosis. The mortality in all cases (operated and not operated) was 28 per cent., and for operated cases 40 per cent.; but during this same period there were 87 cases of croup that were not injected; the mortality in these for all cases (operated and not operated) was 25 per cent., and for operated cases 38 per cent.; therefore, lower than in those treated with serum. Severe diphtheria complicated with croup did very badly with this treatment. All such patients died, and the good result in milder cases is explained by the good type of the present epidemic.

REPORT OF THE MEDICAL SUPERINTENDENTS OF THE METROPOLITAN ASYLUMS BOARD HOSPITALS (LONDON), 1895.

This report embraces 2182 cases of diphtheria treated with antitoxin, 615 deaths, mortality 28.1 per cent. The medical superintendents compare this report with that of 1894, when 3042 cases of diphtheria were treated in all the hospitals of the board without antitoxin, 902 deaths, mortality 29.6 per cent.; but we find that in the Northwestern and Southwestern Fever Hospitals of London, the following results to compare with the antitoxin statistics:

SOUTHWESTERN HOSPITAL.

Year.	Cases.	Deaths.	Per cent.
1892	463	93	22.5
1893	585	159	27.1
1894	546	156	28.5
	1594	408	25.5
1895 (antitoxin)	316	94	29.7

NORTHWESTERN HOSPITAL.

Year.	Cases.	Deaths.	Per cent.
1892	682	138	21.8
1893	1249	332	26.5
1894	1147	309	26.9
	3078	779	25.3
1895 (antitoxin)	363	117	32.2

IN THE SOUTHWESTERN AND NORTHWESTERN HOSPITALS, 1892, '93, '94.

Cases.	Deaths.	Per cent.
4672	1187	25.4

IN ALL THE HOSPITALS, 1895 (ANTITOXIN).

Cases.	Deaths.	Per cent.
2182	515	28.1

There were 225 tracheotomy cases in all the hospitals of the Metropolitan Asylums Board, in 1895, treated with antitoxin; 113 deaths, mortality 50.2 per cent. During the year there were 30 tracheotomy cases in these same hospitals that did not receive antitoxin; 12 deaths, mortality 40 per cent—10.2 per cent. lower without antitoxin than in those treated with antitoxin. This is just the result to be expected when a depressant like antitoxin is added to the treatment of cases of diphtheria so serious as to require tracheotomy. It cannot be said that the tracheotomy cases, which were not treated with antitoxin were mild cases. The tracheotomy cases treated with and without antitoxin during the year 1895 were cases of the same degree, and offered a very good field for comparison of results.

At the Northwestern Hospital, during 1892, '93, '94, there were 215 tracheotomy cases, 124 deaths mortality 57.6 per cent. During 1895 there were 28 tracheotomy cases in this Hospital treated with antitoxin; 18 deaths, mortality 64.2 per cent. During the year 1895 there were 4 tracheotomy cases in the Northwestern Hospital treated without antitoxin; all recovered. Nothing could be more conclusive of the depressing and dangerous effect of the antitoxin in that severe form of diphtheria of the larynx and trachea, which necessitates tracheotomy, than the records of the Northwestern Fever Hospital for the years 1892–'95.

ANTITOXIN IN LARYNGEAL DIPHTHERIA.

About the only claim made for antitoxin at the present time by its advocates is that it has a favorable influence in laryngeal diphtheria; that it relieves stenosis; that it obviates the necessity for operative interference; that the mortality is lower in non-operated cases and operated cases treated with serum; that the tube can be removed

earlier when operation becomes necessary. If antitoxin does not cause a "melting away" of the membrane, as it was first claimed, and does not lessen the duration of the membrane in the visible portions of the throat, what reason have we for supposing that it influences the duration of the membrances in the larynx? The mortality in the Willard Parker Hospital for the first nine months of 1895, in intubation cases treated with antitoxin was 68 per cent., and for the last quarter, 76.9 per cent. During the first quarter of 1896, 67.7 per cent. In April, 72.7 per cent. In the Municipal Hospital, Philadelphia, there were in 71 intubation cases, treated without serum in 1895, 40 deaths, mortality 56.3 per cent. Widerhoefer gives mortality of 43 per cent. in intubation cases before serum treatment.

Von Ranke in 326 intubation cases, mortality 57.4 per cent., before serum treatment. Meisenbach, 57 per cent. in tracheotomy cases in the Philadelphia Children's Hospital, before serum treatment. In Strassburg, in 397 tracheotomy cases (1891–94), mortality was 44.3 per cent. In Geneva (1872–88), mortality in tracheotomy cases, 49 per cent.

In the University College Hospital (London), mortality in tracheotomy cases in 1894 (non-antitoxin year) was 47 per cent.

Is not the very high mortality in intubation cases treated with antitoxin in the Willard Parker Hospital, when compared with the results in intubation cases without antitoxin in the Municipal Hospital, Philadelphia, and the intubation cases reported by Widerhoefer and Von Ranke before serum treatment, and in tracheotomy cases in Philadelphia, and in all parts of the world, before serum treatment, a most positive warning against the use of this treatment in this serious and dangerous form of diphtheria?

Why is it that antitoxin has to-day the hold on the profession which it has? The fame of antitoxin is largely due to the influence of two hospitals—the Empress Frederick Hospital (Berlin) and the Hospital for Sick Children, in Paris. We find that the Empress Frederick Hospital received 875 cases of diphtheria during 14½ months of serum treatment, and that there had been received into the same Hospital during the previous four years only 1063 cases of diphtheria. It is owing to this increase in the number of cases of diphtheria in the various hospitals, and the increase in the number of cases reported as diphtheria, as the result of the bacteriological diagnosis in various cities of the world, that antitoxin is reputed for reducing the death-rate of diphtheria. A careful examination of the subject reveals the fact that the actual number of deaths have not been lessened, but, as stated at the outset of this article, the fame of antitoxin rests on the reported decreased percentage mortality. We find, on examination of the reports from various cities and hospitals, just what was pointed out, with reference to the City of Boston as a whole, and of the Boston City Hospital, that the actual number of deaths have not been lessened.

A CRITICAL ANALYSIS OF DR. WINTERS' CLINICAL OBSERVATIONS ON THE ANTITOXIN TREATMENT OF DIPHTHERIA.[1]

BY JOHN W. BRANNAN, M.D.,
OF NEW YORK;
ATTENDING PHYSICIAN TO BELLEVUE AND THE WILLARD PARKER HOSPITALS.

WHEN asked, some weeks ago, to take part in the discussion of the antitoxin treatment of diphtheria, it was only after considerable hesitation that I decided to accept the invitation. There were several reasons for my hesitation. In the first place, my experience with antitoxin, like that of Dr. Winters, is practically confined to hospital practice, and I believe that the time has passed when hospital experience can contribute much of value to the subject under discussion this evening. One year ago the case was different. At that time we had to rely entirely upon the experience of hospital physicians, who alone had a large number of cases at their disposal. Antitoxin must be administered early in order to get the best results, and we all know that cases do not, as a rule, reach the hospital until several days have elapsed from the beginning of the disease. It is in private practice only that the disease can be recognized and treated early, so that antitoxin may exert its greatest effect. Fortunately we have now the experience of a large number of private practitioners, and it is they alone who can speak with authority on the subject. There are many in this room who have treated from twenty to a hundred cases, and I do not think that either Dr. Winters or myself is competent to express an opinion in their presence on the real value of antitoxin.

Secondly, I can hardly criticize Dr. Winters' views of antitoxin without commenting upon the attitude he has publicly assumed toward the Willard Parker Hospital. If Dr. Winters' position is sound and his observations are correct, the City of New York has been maintaining for

[1] Read in the Discussion on the Antitoxin Treatment of Diphtheria before the New York Academy of Medicine. Abstract made by the author especially for the MEDICAL NEWS.

eighteen months a hospital to which children have been taken and subjected to a method of treatment which is not only useless, but has in many instances led to the death of those children. This has been distinctly stated by Dr. Winters, and cases described by him in detail. As these statements have been made more than once in this Academy, it is here that they should be disproved, if possible.

A few words as to what led to the use of antitoxin in Willard Parker Hospital, and who is responsible for its administration. In the autumn of 1894 the Board of Health, in view of the claims made for it abroad, decided to give it a fair trial in the hospitals under their charge as soon as a sufficient supply of the serum could be obtained. The hospitals of the Health Department differ from the rest of the hospitals of the city, in that they have a resident physician who is directly responsible to the Board of Health, and only indirectly to the Board of Visiting Physicians attached to the hospital. The position of the Board of Visiting Physicians has been rather that of advisers and consultants. We, as a body, were entirely in favor of the step taken by the Board of Health. I state these facts to make it plain that all of the visiting physicians at Willard Parker Hospital stand on the same level with reference to the use of antitoxin at that Hospital. No one of us has any especial interest in its use other than to determine its real value in the treatment of diphtheria. In considering the position which Dr. Winters assumed in his paper, read at the last meeting of the Academy, I wish it understood I am attacking his position, not himself. We believe that he has made a grave mistake, and has done great wrong to the Hospital of which he is one of the physicians, and that his words have caused widespread harm among the people of New York and of the whole country.

Before taking up the evidence submitted by Dr. Winters in support of his views let us see whether he entered upon his observations in the Hospital with a mind open to conviction and free from bias. One cannot read the arguments of any of the opponents of antitoxin without being struck with the fact that they all start with a distrust of the bacteriological diagnosis of diphtheria, and with a reluctance to accept the help offered by the bacteriologists to the clinicians. Dr. Winters is no exception to this rule, and as long ago as December, 1894, it was evident to the other members of our Board that he had strong doubts of the curative power of antitoxin, and was prepared to find it of no value. The systematic use of antitoxin was begun on January 1st of the following year, and from the very beginning he had no faith in its virtues, and was daily proving to himself that he was right in his opinion. He, however, kept his counsel, and no one had any inkling of what was to take place on that memorable evening in April one year ago. After barely three months of observations on some one hundred and fifty hospital cases, Dr. Winters had decided, for all time, that antitoxin was absolutely without value, and in addition produced great harm, even to the extent of causing death in those to whom it was given. From that time to this he has become more fixed in his convictions, and has confirmed them by a personal investigation of the hospitals of Europe.

I, unfortunately, was not present at the meeting last year, but I have read and reread his vivid description of cases which had died of antitoxin poisoning in the Willard Parker Hospital. I shall now take up some of the statements made in Dr. Winters' last paper, first, those bearing on his observations in the Willard Parker Hospital, and, secondly, the ideas which he had gathered on his trip abroad.

All advocates of antitoxin state that it must be given early and in efficient doses in order to produce its full effects. Dr. Winters claims that even when given under these conditions it is not only valueless, but, as seen by its action on mild cases, it even causes the death of the patient. In proof of this he cited twenty-five or thirty cases of favorable prognosis, which had been injected on the first, second, or third day of the disease, and still died. He stated that these cases were taken from the early months of 1895 and 1896—twenty-five or thirty cases. He did not give the full details of the cases; time did not permit of his giving more than what he called the "gist" of the cases. I have collected the records of all fatal cases injected on the first, second, and third day, during the first four months of 1895 and the same period for 1896. There were nineteen in 1895. Twelve were two years of age or less; two were between two and three, leaving only five cases above the age of three years. One was four, two five, one seven, one forty-five. What was the condition of these fatal cases? Twelve had laryngeal stenosis, requiring intubation. Seven of the twelve cases in addition had pneumonia. Five of the non-laryngeal cases also had pneumonia, making twelve cases of pneumonia, and seventeen of the nineteen with either pneumonia or laryngeal stenosis, or both. The single adult case of the group, when he entered the hospital, showed im-

pending delirium tremens. In spite of that the prognosis was put down as favorable.

Now, what was the prognosis stated in those cases? It was stated in the records, instead of being favorable in all, that the prognosis was good in six, doubtful in five, bad in eight.

Let us now take the cases for a similar period in 1896, January 1st to May 1st—some thirty-three fatal cases injected on the first, second, or third day. Seven were less than one year of age, thirteen more were less than two, four just two, five between two and three, making twenty-nine of the thirty-three fatal cases under three years of age, four cases over three years of age. Character of the cases: Twenty-two had laryngeal stenosis, requiring an operation in nineteen, fifteen cases had pneumonia, two suffered from sepsis, one, the only adult, was intoxicated on admission. The prognosis was stated on the records as good in two, doubtful in twenty, bad in eleven. The gist of the cases as given by Dr. Winters was, if I remember rightly, favorable prognosis practically in all; death after injection of antitoxin.

Dr. Winters has stated that since the introduction of antitoxin into the Hospital there had been much greater use of stimulants. Now, it had been the distinct impression of all the rest of the attending staff that less stimulants had been used during the last sixteen months, just as they had found the treatment diminished the amount of iron, etc., used. Through fear that we might have been deceived, I sent to the clerk of supplies to the Health Department, and had learned the amount of alcoholic stimulants used in the Hospital during the antitoxin period, and for a like period just before. Then considering the number of patients in the Hospital for these periods, and the average daily attendance, I found that during the period when antitoxin was in use the amount of alcohol, per patient, per day, was considerably less than one-half an ounce, while during the previous period it was two-thirds of an ounce.

Regarding diarrhea, from which Dr. Winters had said there had been trouble, none of the rest of us had seen it. If anything, there had been more trouble from constipation. The ward charts of perhaps a majority of the patients will show a record of laxatives ordered by the resident physician.

In his paper Dr. Winters has spoken of a very peculiar type of broncho-pneumonia, which he attributed to the dissolving action of the serum on the blood. He had also spoken of the great amount of suppression of the urine, requiring various measures to relieve it, and of increase in albuminuria. Considerable stress also has been laid on cardiac weakness. We have seen no change in these respects in the Hospital. The cases had been just about as they were before, so far as the general condition was concerned, but cases had recovered in greater numbers. They had not been able to say just why, but the mortality had been less. The death-rate in 1894, previous to the use of antitoxin, had been about thirty-four per cent. In 1895, under the antitoxin treatment, about twenty-six per cent.

Dr. Winters had made a comparison at the last meeting which was a little misleading. The figures for intubation the past year, since the introduction of antitoxin, had given a mortality of seventy-two per cent., as compared with eighty-five per cent. in 1894. Dr. Winters had not been very much impressed with this apparent reduction of the mortality to seventy-two per cent., as he stated that a former resident physician at the Willard Parker Hospital had obtained a mortality of only fifty per cent in *laryngeal* cases. Note the difference: *laryngeal* cases, not cases of intubation. Dr. White had made that report, and he did not claim a mortality of only fifty per cent. in intubation cases. I do not know what is the exact mortality from laryngeal cases during the use of serum, but I believe it is between forty and forty-five per cent.

Dr. Winters has spoken of so many cases coming in since January, 1895, with nothing in the throat, but, I have found that according to the records one-third of all the cases in 1894, before the use of antitoxin, had no membrane, or but a small amount, attached to the tonsils. During the spring and the autumn of 1894 I was in the habit of taking students to the Hospital, and on asking the resident physician: "What have we to show the students to-day?" I was met over and over again with the reply that there were two or three new cases, but with nothing in the throat.

It was curious that in this new disease described by Dr. Winters, there had been no *post-mortem* findings. Many *post-mortems* had been made last year. I have attended many, and Dr. Winters also, and portions of the organs were secured by Dr. Winters for private examination. I expected to hear the results of the autopsies and histological investigation. Perhaps these were included in the portion of the paper not read. In my opinion, the lesions were such as had been seen before the use of antitoxin—broncho-pneumonia, fatty degeneration of the heart, and nephritis. A report by Kolisko of Vienna, on this subject is very instructive. Kolisko has been

professor of pathology and pathologist to the University of Vienna since 1882. He had made some thousand autopsies on diphtheria. Since the use of antitoxin he had made seventy-five autopsies, and was convinced that the serum influenced the diptheritic process most favorably. The membrane was more easily separated, and was often loosened. The same thing had been seen before the use of antitoxin, but never to the same extent, or so soon after the onset of the disease. It was necessary, however, that a certain period of time should have elapsed after the injection, and that the dose should reach a certain amount, for if it were too small, separation of membrane would not be observed. When the process had penetrated deeply, the effect was less marked or *nil*. The anatomical changes in the internal organs were the same, broncho-pneumonia, fatty heart, changes in the kidneys.

Kolisko also stated that at times, before the use of antitoxin, all cases would show nephritis, then there would be a period when there would be none, and it was so since the use of antitoxin. He was positive that antitoxin had no effect in producing nephritis. Kolisko lays stress upon the important clinical fact that the diphtheritic process may remain localized at some hidden point, as in a crypt of the tonsil, or in the nasal cavity, and then suddenly break out with great virulence and fatal termination. Such cases illustrate how we may be deceived when we believe that we are injecting a case on the first or second day of the illness.

Dr. Winters quoted a number of the physicians attached to the hospitals of the Health Department as expressing themselves unfavorably to antitoxin. Some of the physicians had gone so far as to say, according to his quotation, that they knew cases which had died from the use of antitoxin. It would seem to prove that Dr. Winters does not realize the significance of his own utterances when he attributes such statements to men who hold official places under the Health Board. I have been told by many of these men that Dr. Winters had not altogether understood their views.

I shall now refer briefly to the evidence collected by Dr. Winters in Europe. Regarding some who were supposed to be the opponents of antitoxin, Hansemann, who was supposed to reflect the opinion of Virchow, had had nothing more to say when Virchow, on observing the results at the Berlin Children's Hospital, was so struck by those results that he was compelled to change his opinion, and became a convert. Kassowitz of Vienna, was a disbeliever after an experience with eight cases, but he had had nothing to say since, after having been answered by Widerhoefer. Lennox Browne had once been a strong opponent of antitoxin, and is probably still skeptical. Two of the men quoted by Dr. Winters as having been opposed to antitoxin, one in Paris and the other in England, were young men, and had not had that experience with diphtheria previous to the introduction of antitoxin to enable them to appreciate the improved results under the latter. Variot, who had been represented by Dr. Winters as a firm believer in antitoxin, but was now opposed to it, had always been inclined to dwell upon the unfavorable side of antitoxin, as is shown by the simple titles of his papers.

Toward the end of his paper Dr. Winters had stated that all the earlier claims for antitoxin had been abandoned. I can hardly believe that he had really meant to go as far as that. I have looked over the literature of the last few months, and have here the strongest testimony from various parts of the world—Massachusetts, Germany, England, and Japan. These papers, from which I shall read a few extracts, all speak of favorable results from antitoxin, both in the treatment of diphtheria and when used for immunizing purposes.

In the foregoing analysis of Dr. Winters' clinical observations, I have not attempted to estimate the exact value of antitoxin in the treatment of diphtheria. I have kept steadily in view the task I set myself at the outset—the task of proving that the children in the Willard Parker Hospital have not been injuriously affected by the administration of antitoxic serum. This purpose I believe I have accomplished. Incidentally, it has also been demonstrated that the position of Dr. Winters in regard to antitoxin does not stand the test of critical examination. His descriptions of cases of antitoxin poisoning in the Willard Parker Hospital have no sound basis of fact, and they have not been confirmed by other observers, though they were published to the world more than one year ago.

DIPHTHERIA WITH AND WITHOUT ANTITOXIN.[1]

By WM. L. STOWELL,
of New York.

The basis of this article was a study of 240 cases that the author had treated in dispensary practice during the years 1888–1895 inclusive, *without antitoxin*. He gave results of treatment

[1] Read at the meeting of the New York Academy of Medicine, June 4, 1896. Abstract made by the author especially for the Medical News.

reported by other observers for the same period, and a *resume* of results with antitoxin in the same class of cases and in his hospital service.

One hundred and seventy-six of his cases occurred up to March, 1895, and were reported last year in the *Medical Record*. The mortality was thirteen per cent., without eliminating those who died within twenty-four hours. Dropping such, the rate was ten per cent. As these were in part before the days of bacterial culture, he checked his figures by counting all the tonsillitis cases for the same time. Of these there were 551. Of the tonsillitis cases, many had a quantity of exudate that was membranous, but his aim seemed to be to avoid a diagnosis of diphtheria so far as possible. During 1895, he treated sixty-four cases of diphtheria, with a mortality of 7.8 per cent. This great fall in mortality was not due to change in method, for there was none, but to the large number of mild cases. In fact, only two were severe enough to call for intubation. The number of mild cases was attributed to the care with which all the physicians now report exudates as possible diphtheria.

The total figures were 240 cases in eight years; mortality 11.25 per cent., without eliminating. This was better than the health inspectors report on similar tenement cases given antitoxin. Their figures were 255 cases, 15.69 per cent. deaths. Smith, Billington, and Stowell together had published 495 tenement cases, with a mortality of a little over 10 per cent.

The Leipsig physicians, a few years ago, collected 1141 cases, with a mortality of 15 per cent. The *British Medical Journal* had also collected 1321 cases, with 14 per cent. mortality, before antitoxin days. These reports the author considered a better standard for practitioners than hospital statistics.

It was noted as a remarkable coincidence that the number of diphtheria cases reported in this city increased markedly from the beginning of cultures by the Health Department. Previous to 1893, the reports had been 4359, 4974, and 4654 per year, but the number then rose to 6469, 9155, and 9925 for the last three years. Similar results were seen in the official reports from Berlin and Paris, and in all cities where cultures are made by the health boards.

The author laid stress on the fact that many reported cases never presented clinical symptoms. He mentioned a family in which a boy had marked diphtheria, and where four other members were declared to have the same, even after the rooms had been fumigated. These four persons showed no evidence of disease, and did not take medicine. He instanced the case of the New York Infant Asylum, in which nearly half the inmates showed diphtheria bacilli in their throats when some children in the house were really down with diphtheria. These are the cases that swell the reports and cause a decrease in the ratio of deaths.

Klebs-Loeffler bacilli have been found on the floor of wards, on scrapings from the shoes of attendants, on the hair, etc. Roux found them in twenty-six of fifty healthy children whom he examined. Something more than the presence of germs is necessary to constitute the disease diphtheria. While the author has made a distinction in name between exudative tonsillitis and diphtheria, he has treated the former, like the latter, with iron and peroxid of hydrogen.

Returning to figures, the unfairness is shown of comparing 1895 with 1894 as to results, and claiming that antitoxin is the cause. In 1894, 2359 persons died in this city from diphtheria. This is the *greatest* fatal number on the city records. It is twenty years since 2300 such deaths occurred, and 2100 has been reached but twice in that time; 1634 died of diphtheria in 1895. This is just the average for a decade previous to 1894, but of course must be increased slightly for increasing population. A mild year is therefore shown to be compared with the worst possible. A fall of 600 or 800 has occurred many times in the mortality returns, when no change of treatment could be thought to influence it.

The official reports of the Health Department regarding Willard Parker Hospital were then quoted. As there given, the mortality has averaged twenty-four per cent. since 1886. Great gains are claimed for antitoxin, while the fact is forgotten that three times since 1886 the mortality was less than in 1895.

The London Asylums Board hospitals reported a mortality of 30 per cent. in 11,000 cases treated during six years ending with 1894. In 1895, the same hospitals treated 2182 cases by antitoxin, with a mortality of 28 per cent. They add to this number 1347 cases treated without antitoxin (claimed to be mild, etc.), and report a death-rate of 22.5 per cent. In order to give the low rate for antitoxin, they report a series of cases of which more than one-third had no antitoxin.

The report of Boston City Hospital for December, 1894, and January, 1895, was cited. There, 80 cases with antitoxin gave a mortality of 16 per cent. At the same time, 40 cases had no antitoxin, and 30 per cent. of them died. The reason given is "that 5 patients were moribund on entering, that

6 were too far advanced in the disease, and because, owing to the insufficient supply of serum, it was thought best to withhold it for cases giving promise of better results."

The refusal of a health inspector to inject cases on Randall's Island, "because it would increase the percentage of deaths," was cited. The doctor did not blame either of these men, but cited the cases to exemplify the fact that no cases are too bad for comparison with antitoxin, but that it is given in early and favorable cases. The advantages of early treatment have been insisted upon by all writers and advocates of all treatment.

Examples of success without antitoxin were then given.

Hübner reports 117 cases with antitoxin, mortality 10.2 per cent; 46 complicated cases, with mortality of 21 per cent. Yet in 1889 he reported that by carbolic acid injections into the tonsil he had reduced the mortality of scarlatinal diphtheria from 35 per cent. to 10 per cent.

Hennig, in a collective report, gives 1054 cases by same treatment, mortality 2.7 per cent.

Seibert's mortality with chlorin injections was 5.7 per cent.

In the New York Foundling Asylum, the mortality was 52 per cent. in 1891, and 38 per cent. in 1892. This fell to 27 and 24 per cent. for the next two years under papyotin and hydrogen peroxid, but rose again to 45 per cent. when treatment was changed to antitoxin.

Loeffler uses alcohol, tolnol, and tr. ferri chloridi locally, and reports 71 cases in private practice with no death; also 30 cases in hospital with 16 per cent. mortality.

Jacobi reports 40 consecutive cases with 2.5 per cent. of deaths under mercury and iron treatment. In all, the author had on short notice compiled a table of more than 7000 cases treated without antitoxin, with a mortality of 8.8 per cent. This appears to show treatment better than antitoxin. It actually shows that when men are following their cases closely and treating early and often, they report good results.

The statistics in the paper of Dr. Welch, contain all the valuable statistics for antitoxin to July, 1895, but here the testimony is only by antitoxin advocates. Yet by reference to the original articles it is seen that many eliminate moribund cases, and include all suspected ones.

Fischer's report is 225 cases mortality 15.5 per cent., *versus* "about 55" previously. Accuracy *versus* a guess, and at the same time he states "I have reduced my mortality somewhat by not injecting hopeless cases."

Bigg's report is 225 tenement cases, mortality 15.69 *versus* 25 to 45 per cent. without antitoxin. The published records of tenement cases, according to the author, are but 10.55 without antitoxin.

The reports from Boston City Hospital, on analysis, show that one-third of the cases were eliminated during six weeks noted, and that 30 per cent. of these died.

The table concerning operations is remarkable. Kraske is credited with 16 tracheotomies with antitoxin; mortality 31 per cent.; 12 tracheotomies with no antitoxin, previously 25 per cent. mortality. His results were 6 per cent. more favorable without than with antitoxin. Yet we are told that "his cases were so few as to have no significance." If so, fifteen reports in the table should be set out, as they are based upon the same or a smaller number of cases.

The mention of nephritis and broncho-pneumonia is striking in some reports. At the Foundling Asylum, 79 per cent. had broncho-pneumonia with the antitoxin, whereas, 40 per cent. had pneumonia in 1894 without antitoxin. In the Willard Parker Hospital, 53 per cent. of antitoxin cases had pneumonia *versus* 16 per cent. in 1894 without antitoxin.

The *British Medical Journal* reports fifty cases in 1894 with 1.6 per cent. broncho-pneumonia *versus* 3.6 with antitoxin in 1895. It is fair to state, however, that in the Williard Parker Hospital the ratio of stenosis and septic cases fell as much as the pneumonia advanced.

Referring to his own cases again, the author said that the inspectors had reported 14 of the 64 cases as not having Klebs-Loeffler bacilli. However, two of these were fetid cases, two had extensive exudate and nose-bleed, another had exudate on the palate and uvula, as well as tonsils. In two, the germs were found when re-examination was asked. One woman complained of much irritation in her throat while tending her four children, all sick with diphtheria, one of whom died. Though no membrane appeared, a culture was made with negative results. Two died without culture reports, yet the bureau of records did not discredit the diagnosis.

As a method to convince himself of antitoxin virtues, the author stated that he had used the remedy in all his hospital cases, and intended to use it also in all dispensary cases for a year, that full years might he compared. Thus far, his mortality in the tenements with antitoxin had been 12½ per cent. In the infant hospital 53 per cent.

If the mortality of 7.8 for 1895, can be cut in two, as claimed, and only 3.5 prevail for 1896, the author will be an advocate of antitoxin. This review of personal experience and from reports of both sides up to the present, lead to the following conclusions:

That diphtheria is very variable in extent, both epidemically aud clinically.

That the distinction, true or false diphtheria, requires as much care bacteriologically as clinically. One culture is not enough.

That the present unusual number of cases reported is due to recording bacterial cases without symptoms.

That the falling *ratio* of deaths is due to the same causes. The total deaths do not fall as the ratio does.

That cleanliness and ventilation will immunize as well as serum.

That selected cases under faithful treatment of any reasonable kind lead to success.

As Simon well says the efficiency of the remedy not only, but fidelity in its use, gives results. The present antitoxin enthusiasm is born of bacteriology and elimination.

PROFESSOR BRUNS of Tubingen, has been elected president of the German Surgical Congress for next year.

STATISTICS OF DIPHTHERIA.[1]

BY C. G. COAKLEY, M.D.,
OF NEW YORK.

THE study of the statistics of diphtheria were divided into two periods, an early period prior to the year 1894 and a late period since the beginning of that year. The diagnosis of diphtheria in the early period was shown to be uncertain, as it depended upon certain constitutional symptoms which varied considerably, and upon the presence of a pseudo-membrane. From various motives, physicians during that time failed to report their mild cases, so that the mortality rate was made to seem higher than it really was.

The late period (ushered in by the establishment in cities of means for affording the general practitioner opportunities of having bacteriological examinations of cultures taken from patients' throats and the general interest in diphtheria due to the introduction of the antitoxin treatment) found a more exact method of diagnosis, and many cases that in the earlier period were not

considered to be diphtheria were found to be such. The accompanying table is taken from the official health reports of these cities:

The column "Number Dying per 10,000 Inhabitants" is more reliable than the column "Per Cent. Deaths" as a means of indicating the fatality of diphtheria, for "Per Cent. Deaths" depends greatly upon the "Cases Reported." The failure to report mild cases ending in recovery in the early period and the finding of others (mostly mild cases also ending in recovery) in the late period markedly effect "Per Cent. Deaths" without perceptibly affecting "Number Dying per 10,000 Inhabitants." Could these errors be eliminated, the figures in these two columns ought, with slight variations, to increase or decrease in the same ratio.

Examination of this table shows in all the cities

1. Great increase in the number of cases in 1894 and 1895.

2. Variations in the number of deaths in different years.

3. Per cent. deaths varying, but very low in 1895.

4. Number dying per 10,000, regular variation in rise and fall.

5. That while per cent. deaths *diminished* in 1894, number dying per 10,000 *increased* greatly.

6. While there is a fall in number dying per 10,000 between 1894 and 1895, yet in all but Boston greater falls have occurred before antitoxin was used.

7. Comparing the four columns for each of the cities for the three years 1893, 1894, and 1895, one fails to see that many lives have been saved, although the "Per Cent. Deaths" has been markedly lowered.

8. Diphtheria in 1894 was severe, as indicated by the deaths and number dying per 10,000. Did that epidemic die a natural death, or was it helped out of existence by antitoxin?

As a result of our study of the statistics of diphtheria, not only in the cities above named, but also in many others here and abroad, we find the conditions so different in the early and late period, as we have divided the disease, that any comparison of the death-rate of the latter period with the death-rate of the former period will be apt to lead one to erroneous conclusions.

M. GUINKOFF, at a recent session of the French Academy of Sciences asserted that he had been successful in photographing his own retina. He is now perfecting his method, which must be regarded as an important addition to our present means of accurately recording clinical observations.

CLINICAL MEMORANDUM.

MIND AND WORD DEAFNESS AFTER DEPRESSED FRACTURE OF THE SKULL WITH SUBCORTICAL HEMORRHAGE—OPERATION; COMPLETE RECOVERY.

By J. T. ESKRIDGE, M.D.,
OF DENVER, COL.;
NEUROLOGIST TO THE ARAPAHOE COUNTY AND ST. LUKE'S HOSPITALS.

FRANK P., twenty-three years of age, single, born in Bohemia, miner by occupation, was admitted into the surgical wards of the Arapahoe County Hospital on the evening of September 21, 1895. The family history, so far as ascertained, was good. The patient lived in his native land until he was thirteen years of age, when he came to the United States. During his youth he acquired a good knowledge of the Bohemian language for a man in the lower walks of life, and after coming to this country he attended school and spoke the English language almost as fluently as his native tongue. For a number of years he has worked in the coal mines of Colorado. He has been addicted to the excessive use of alcohol and occasional venereal excess: but he denies syphilis. He stated that he was never ill until the beginning of his present trouble.

On the 21st of September, 1895, in a drunken brawl, he was struck on the head just above the left ear with the butt of a revolver, or with a coupling-pin, and felled to the ground. On admission into the Hospital a few hours later he seemed dazed and confused, answered questions in English quite intelligently, but slowly. His temperature was 99.4° F. in the left axilla; 99.2° F. in the right; pulse, 80; respiration, 16. The next morning he was able to give some of the details of the injury, but by the afternoon of the 22d he ceased to be able to speak in English, and while he used words and phrases in the Bohemian dialect, they did not convey any meaning when translated into English.

At 8.30 P.M., I was asked by Dr. Rogers, who was attending to the surgical cases of the Hospital during Dr. Parkhill's absence, to see the patient in consultation with him. His temperature remained about the same as it was at the time of his admission, the pulse had fallen to 66, and respiration was 18, but regular. There was no paresis or paralysis of any muscles, the superficial reflexes were absent and the deep reflexes were decidedly lessened. The eye-grounds were normal. The patient watched me during the examination, and seemed to realize in a confused way what was going on. When I spoke to him he appeared to hear, but would answer in Bohemian, and sometimes in English, using words entirely irrelevant, and when shown things, such as a watch or keys, he gave no evidence of recognizing them; nor did he seem to understand anything that was said to him. When told, either in English or Bohemian, to put out his tongue, he made no effort to comply with the request. The mental confusion was so great that it was impossible to determine how much of his condition was due to the

localized injury in the left temporo-sphenoidal lobe, and how much to general brain disturbance.

After a careful examination I came to the conclusion that the patient could hear, but that sounds were unintelligible to him, and he did not seem to realize the use of things. There was such evidence of cerebral compression that Dr. Rogers decided to operate at once. On enlarging the wound, a depression of the skull above the left ear was found. The depressed bone was rectangular in shape, with the long axis extending from before backward and measuring in length 2½ and in width 1¼ inches. The center of the depression was on the auriculo-bregmatic line. The lowest portion of the fracture was a half inch above the base line of the skull. The fractured portion was entirely detached from the surrounding bone and depressed from one-fourth to three-eighths of an inch below it. On removing the depressed bone, the membranes seemed normal, and very little extravasated blood was found. As the brain pulsated about normally, it did not seem necessary to open the dura. The base of the skull could be examined readily by the finger, and the opening in the bone appeared to be about opposite the middle third of the second and third temporal convolutions.

The patient reacted well from the operation and on the next morning desired to sit up in bed, so that restraint was required to keep him in the recumbent posture. He looked confused, and did not seem to understand questions or the use of things. When he was spoken to, he would utter one or two disconnected words in Bohemian, and not infrequently would say "yes" in English to everything. The temperature, pulse, and respiration remained nearly the same as they had been before the operation. On the evening of the 23d, about twenty-two hours after the operation, his temperature in each axilla was 100°, pulse 60, and respiration 20.

He slept quite well during the following night, and remained in about the same condition, except that the temperature fell to normal, until four days later, September 27th, when, at 2.30 A.M., he had a violent convulsion in which the trunk muscles seemed to be more affected than those of the limbs. The head was retracted and the eyes were rolled upward to their fullest extent. The convulsion lasted two or three minutes. After this the general condition was about the same as before the convulsion. He was still unable to understand any question or to communicate any of his desires to the nurse or physician. The temperature remained about one degree above normal, but the same in each axilla. The respiration and pulse were normal. I tried repeatedly to examine into his aphasic condition, but was foiled on account of his mental confusion.

On October 4th, at 4 P.M., he had a second convulsion, which was preceded by a loud cry, and when the nurse reached his bedside she found him frothing at the mouth, breathing stertorously, and eyes turned upward. The convulsive movements were general and involved all the limbs. At 11.25 P.M. he had another convulsion, similar in almost every respect to the one that occurred during the afternoon.

On October 5th I saw the patient about noon in consultation with Dr. Parkhill, who had returned and was in charge of the surgical ward. Although no distinct form of sensory aphasia could be made out, it was found that he could utter sounds and words quite distinctly, and that he endeavored ineffectually to communicate his thoughts by speech. It was apparent that he heard my voice, but words to him were apparently meaningless. The ticking of a watch held to his ear, the ringing of a bell, or the jingling of coins seemed to convey to him no meaning. The words that he used, both in English and Bohemian, were so jumbled that they conveyed no meaning. He evidently could hear, even when the right ear was closed, as he looked in the direction from which sounds came, but he could not distinguish differences between the sounds of words, or differences between sounds other than words or speech. It was my belief that a lesion existed in the temporo-sphenoidal lobe, and on my recommending an exploratory incision into this portion of the brain, Dr. Parkhill decided to operate.

On exposing the dura the whole external surface of this membrane over the surface laid bare by the fracture was covered by a layer of organized lymph, at least one-sixteenth inch thick. The lymph was carefully scraped off, but still no pulsation of brain tissue could be felt or seen. The dura was incised and the cortical substance appeared healthy except that it did not pulsate. On cutting into the temporo-sphenoidal lobe at about the center of the wound, dark, partially clotted blood ran out, and on enlarging the opening with a pair of forceps, considerable dark fluid and clotted blood escaped, together with some softened and broken-down brain tissue. The hemorrhage was entirely subcortical and involved the white substance immediately beneath the posterior portion of the first and second temporal convolutions. The wound in the brain was irrigated with sterilized salt solution and the opening in the dura and scalp were closed, except a small space which was left for drainage.

The patient remained in about the same condition for twenty-four hours after the operation that he had been in previous to it, except the right lower side of face was paretic. On the afternoon of the next day, or October 6th, the nurse asked him to turn over in bed and at the same time made a motion in which direction she wanted him to turn. He obeyed her request. In the evening when shown a watch he said "One-half past." The watch at the time indicated 6.30 P.M. He could not be gotten to tell the hour. October 7th, 11.30 A.M., I found that he could read aloud, but could not pronounce long words, nor did he seem to understand what he read. The right side of the face was slightly paretic. It was impossible to get him to protrude the tongue, as he did not seem to understand what was wanted of him, even when I wrote the request and then protruded my own tongue. He seemed much brighter, and when I showed him my watch, which indicated 12.15, he said, "It's exactly a quarter of an hour." When the minute hand had reached the even hour I again showed him the watch, but he seemed to be unable to tell the time of day. When the watch was first shown him he said "pretty

fine," and when it was placed against his ear he said "going pretty well." When he was given asafetida to smell he said "pretty bad," and on giving him milk to drink he said "good," but he did not seem to understand anything that I said to him. He was evidently word deaf, but not word blind, as he could read slowly quite well, although he did not appear to appreciate what he read.

It was difficult, or almost impossible, to determine whether he recognized objects presented to him by the various senses, as he did not seem to be able to read understandingly. Besides, the local injury to the temporosphenoidal lobe, he was suffering from the general effects of traumatism of the head. He could not be induced to name any object, but he appeared to know the use of some objects, as evidenced by his answers when a watch was shown him or placed against his ear (left one). Spoken words had no meaning to him. He read slowly, but distinctly and connectedly, writing and printing, but it was doubtful whether he understood what he read. He made several ineffectual voluntary attempts to write, but could not combine the letters so as to make sense, although he could form the letters well. He could copy single words and read them, but would attempt nothing more, as he seemed to be exhausted. He could not write from dictation, because he could not understand what was said to him. It was observed that he never spoke voluntarily. The right side of the face was still paretic.

On the 8th he was able to recognize letters and call their names, and to write figures and read them. He was able to add two and two, but could not multiply. When shown playing cards he simply called them by the number of spots on them. When shown king, queen, and jack he said one. Cards did not seem to make any mental impression upon him except of number. He was unable to recognize a letter when it was traced with his finger. Re-examination of the eyes showed fundi entirely normal. It was impossible to test the visual fields. The right side of the face was more paralyzed than it was a day or two before, but he now protruded the tongue in the median line.

October 9th remained in about the same condition.

On the 10th he understood what was said to him and repeated a few words. If a thing was held up and a name suggested, he assented to it, giving assent to all names, the wrong name as well as the right one. When asked how he felt he said, "Better." Have you headache? "Yes, a little." Where? He put his hand to the left side of his head. What is your name? "Frank Pezel." He was able to name a watch and tell the time of day. The right side of face is more paretic than it was yesterday, but he is able to protrude the tongue in median line.

On October 11th I made a prolonged and systematic examination to determine the degree and character of the aphasia. This was the first day that his mental condition appeared sufficiently clear to make such an extended examination possible. It was impossible to determine whether he recognized all objects seen. This power existed for the most familiar ones. On testing his power to recognize objects presented to him by the other senses, varying degrees of apraxia were found present for some. When a watch was placed against his ear he recognized it at once. On covering his eyes and allowing him to feel objects, he became confused. The senses of smell and taste did not seem to convey to his mind as definite impressions as those of hearing and sight. Some things he used correctly and others wrongly in feeding himself.

His power to recall the names of objects presented to him, by the various senses was defective for many things. By the sense of sight he could recall the names of all familiar objects, such as pencil, coins, watch, knife, tobacco, etc., but those less familiar such as book, scissors, needle, spool, pin-cushion, etc., he frequently made blunders in trying to name them. Watch and coins he recalled the names of when he heard them, but bell and keys were sometimes wrongly named. He made many mistakes in naming objects presented to him, by the senses of feeling, tasting, and smelling. Tactile sense seemed to convey to his mind the least definite impression of all the senses. He understood sounds other than speech better than those of speech, and rarely made a mistake in interpreting familiar sounds. His power to understand speech was very imperfect. He showed no apparent intelligent appreciation of speech, except in a few direct questions that related to his own condition, such as "What is your name? Have you headache? Are you hungry?" etc. To every other question or request he would answer "German." He manifested no appreciation of music. It was learned later that he had never known anything of music. He was unable to call to mind objects named, and consequently could not point them out. He invariably recognized his own name when it was spoken, but other names, such as nurse, doctor, etc., he did not recognize unless they were repeated over several times. He did not recognize a word spelled aloud. So far as I was able to determine, he could not call up mentally the sound of a note, figure, letter, or word, but on this point I could not be certain as it was difficult to get him to comprehend what I desired.

He recognized figures and letters, pronounced words shown him, could read printing and writing aloud, but did not seem to understand what he read. He was unable to recall the objects the names of which were seen. When given a pen and requested to write, he wrote his name, but could not be induced to write anything else. He attempted to write every time that he was requested, but after hesitating a while, his name fairly well written was the invariable result of his effort. He could not write at dictation. He wrote from copy, quite well, both printed and written, and converted printing into script.

In testing his ability to write the names of things seen, heard, felt, smelt, and tasted, he wrote the name of only one. This was whisky. He was shown a pencil, and requested to write its name. He shook his head. He was given sugar to taste, cologne to smell, a pencil to feel, and a watch was held against his ear, but he did not attempt to write the names of any of them. When whisky was presented to him by any of his senses, it invariably caused him to smile, and immediately on my requesting

him, he wrote the word "whisky." He read aloud what he had written, but evinced no evidence of understanding what he had written except the word "whisky," and possibly his own name, although it was by no means certain that he understood what it represented. It was learned afterward that he was very fond of whisky. He could not apparently recognize a letter when his index finger was made to trace it. His mental condition was such that I could not determine whether he could mentally call up the appearance of a figure, letter, or word.

There was no defect in voluntary speech except that it was slow. He could repeat words after another, provided they were uttered very slowly. There was a tendency with him to repeat the first word of a sentence two or three times in repeating a sentence after me. The patient recognized some of his mistakes in writing, but seemed unable to correct them. There appeared to be no special difficulty in the use of nouns, verbs, or other parts of speech. He understood and used gesture expression in speech. He could count, both money and in numbers. He was unable to play a game of cards. He did not seem to be able to recognize differences between cards, but when different cards were shown him he called out the number on the card, and all were spades to him. After he recovered he showed quite a fondness for various games with cards. There was no defect in the field of vision. Sensation was perfect throughout the body.

On October 15th he manifested no difficulty in recognizing objects and their uses. He quite readily named most objects presented to him through the different senses. The only trouble apparent in understanding speech was that the first word or words of a sentence appeared to make the most impression on his consciousness, and these would be repeated two or three times. He read printing and writing quite well, but did not show a comprehensive appreciation of what he had written. He could recall the names of most objects presented to him and wrote them. He wrote at dictation imperfectly, as the first word or words of a sentence were repeated several times in writing a sentence. He understood cards and played games with them.

October 22d, no appreciable defect in speech. He said that he did not fully realize where he was and what had happened until a few days ago. He did not remember that he had seen me, and that I had examined him prior to October 15th. He said when he fully regained consciousness that he found he could not speak as formerly in Bohemian. Before his injury he had spoken as well in Bohemian as in English, but now it was quite difficult for him to think in his mother tongue.

Throughout the period of his illness, beginning September 21st, and ending about October 15th or 20th, his temperature was practically normal, and equal on the two sides of the body, except on the occasions noted in the clinical history just given.

The points of special interest in the above case are, the localizing value of the aphasic symptoms, the external pachymeningitis and convulsions, the mind and word deafness, and the partial loss of the language which he had first learned, and which he had used exclusively for the first thirteen years of his life.

On September 22d, when I was asked by Dr. Rogers to see the case with him, by the auditory defect of speech alone, before the wound was exposed, the lesion was located in the first and second temporal convolutions. On finding a depressed piece of bone lying against these convolutions, without any extravasation of blood, it was thought probable that there was no deeper lesion. Still the auditory speech disturbance did not improve. A few days later, when the general convulsions began, it was decided by Dr. Parkhill to reopen the wound. On exposing the dura and finding it covered with recent exudate, partially organized, this seemed to be sufficient to give rise to the convulsions, but I argued that the pressure from this was not great enough seriously to interfere with the function of the temporal convolutions. After the dura had been cleansed and incised, no exudate was found on the internal surface of this membrane, and no cause for pressure on the cortical substance of the brain was discovered. It became evident that there must be some subcortical lesion to account for the mind and word deafness. The pulsation of the brain was just apparent, but very feeble. At my request Dr. Parkhill cut into the brain substance and exposed dark, partially clotted blood. After this, when the broken-down brain substance had been removed, improvement became apparent as soon as the effects of the anesthetic had worn off, and two or three days later the mind deafness had greatly lessened, and soon disappeared entirely. The word deafness, on the other hand, remained for at least three weeks longer. Auditory speech disturbances as localizing symptoms will be discussed at greater length in the summary which is to follow the report of this series of cases.

How are we to account for his failure of memory for his mother tongue to a greater extent than for the language that he had acquired after his thirteenth year? In amnesia it is found that memory fails most for things recently acquired, and for those that were learned at more or less remote periods it may be well preserved. In senile dementia the incidents of early childhood and youth may be remembered with great vividness, and prattled about by the dement, yet he may not be able to tell what he has eaten an hour before. In the delirium of fevers, persons, who are foreign born and who may not have had occasion to speak their native tongue for years, will speak exclusively in the language of their childhood. The manner in which memory fails is so invariable that in a case of suspected feigning of amnesia, if recent events are well remembered and the mind is a blank for things learned in early life, we do not hesitate to pronounce the suspect an impostor.

Is this case, then, an exception to the rule? I think not. During the patient's delirious state he talked almost exclusively in the Bohemian language, and only used the English after the receipt of the injury, during the time intervening between this and the development of the delirium, and again as the delirium began to subside, English was substituted for the Bohemian. It

was not until several days after recovery appeared complete that he volunteered the information concerning the difficulty he experienced in thinking in his mother tongue. On inquiry I found that during the five years he had been in Colorado he had not had occasion very frequently to speak the Bohemian language, and from his thirteenth year up to the time he had come to Colorado he had spoken Bohemian only at home, and English with his playmates and school companions.

The facts are these, in his normal condition, he could talk best in that language which he used most, and for a number of years had employed almost exclusively, but in his delirious state the brain-cells reproduced from the memories made upon them when they were most impressionable. The injury to his brain had left him weak, and voluntary recollection was best for those things with which he was most familiar at the time.

While his condition of memory impressed me as being peculiar at the time he volunteered the information concerning it, yet on reflection all mystery disappears.

MEDICAL PROGRESS.

To Preserve Rubber Instruments it has been recommended that they be kept in a three per cent. solution of carbolic acid. Should they not be used frequently, they should, from time to time be removed and stretched.—(*Zeitschr. f. Krankenpfl.*, April; *Munch. med. Woch.*, 1896, 16).

Osteitis in the Course of Typhoid Fever Disappearing with Defervescence.—At a recent meeting of the Societé des Hopitaux WIDAL (*Presse Médicale*, 1896, No. 26, cxxvi) reported a case of typhoid fever in which on the twenty-seventh day of the attack, with the temperature hovering about 102.2°, a swelling half as large as a hen's egg was observed arising from the left ninth rib posteriorly, just below the angle of the scapula. The mass was unyielding to pressure and as hard as bone. The overlying tissues were somewhat reddened. For several days the formation continued to increase in size; then as the temperature declined it grew smaller and smaller, finally disappearing entirely in the first days of convalescence and leaving a slight depression. It was pointed out that the inflammatory lesions of bones associated with typhoid fever appear, as a rule, after convalescence has been established, and not, as in the case reported, in the course of the attack.

The Influence of Injections of Serum upon Articular Rheumatism.—WEISS (*Centralblatt für innere Medicin*, 1896, No. 17, p. 417) reports the results obtained in the treatment of acute articular rheumatism from the employment of blood-serum secured through venesection from individuals convalescent from that disease. Ten cases were thus treated, twenty-two injections in all being given. Following nine injections the articular affection was favorably influenced, as regards both swelling and pain. After six injections no influence upon the morbid process was observed, and following three the condition was aggravated. In seven instances the injection was followed by the reduction of temperature and sweating. The amount of serum employed varied, on an average, from a dram and a half to two drams and a half.

THERAPEUTIC NOTES.

Treatment of Gastric Ulcer Complicated by Hemorrhage.—The patient should assume the recumbent posture, with complete rest, not leaving his bed for any purpose, and the stomach should so far as possible be immobilized. Complete abstinence by the mouth should be observed, not even ice being permitted. An ice-bag or cold compress may be applied to the epigastrium with advantage. Should the bleeding persist, a syringeful of the following solution should be injected beneath the skin over the region of the stomach:

℞	Dialized extract of ergot . .	15 grains
	Distilled water	75 minims
	Carbolic acid	1½ grain

Nourishment is to be withheld even by the rectum. If the patient is debilitated or the nutritive condition is alarming, recourse may be had to an enema of the following constitution:

℞	Milk	8 ounces
	Yolk of egg	number 2
	Sodium chlorid . . .	a teaspoonful
	Red wine . . .	a tablespoonful
	Starch	a tablespoonful

This is to be warmed and injected slowly twice or thrice daily after a lavement of water. To overcome pain codein hydrochlorate or phosphate may be employed in dose of from ½ to ¾ grain. If constipation demand intervention enemata of soap-suds, glycerin, olive oil, or castor oil may be employed. The patient remains abed for about a week thereafter, the diet consisting of milk and lime-water or milk with a little tea or coffee, beef tea, bouillon, peptones, meat solution, emulsions of the white or the yolk of egg, carbonated waters; but excluding cocoa, chocolate, and wine. In the second week following the hemorrhage eight ounces of hot Carlsbad water are to be administered night and morning, with from a dram to an ounce of Carlsbad salts. Warm compresses are to be kept applied to the abdomen to the point of inducing redness of the skin.—*Journal de Médicine de Paris, 1896, No. 14, p. 168.*

Treatment of Attacks of Migraine.—1. Diminish the hyperesthesia of the painful area by a spray of some local anesthetic.

2. Immediately afterward practise compression of both temporal arteries, preferably by means of rings of cork held in place by a gauze bandage.

3. At intervals of two hours for four doses a cachet is given containing of

Antipyrin	7½ grains
Spartein sulphate . . .	⅓ grain
Caffein citrate . . .	1½ grain

4. If there is gastric derangement the foregoing combination may be administered by enema.—*Critzmann, Presse Médicale, 1896, No. 31, p. 185.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

SATURDAY, JUNE 20, 1896.

THE PATHOLOGY OF ADDISON'S DISEASE.

WHILE the pathology of the symptom-complex covered by the designation Addison's disease is yet involved in obscurity there is growing reason to believe that the disorder is dependent upon disease of the suprarenal bodies—in some instances of an obvious nature, in others beyond our powers of observation. Further, in a certain proportion of cases changes in the suprarenal bodies are found in the absence of recognized symptoms of Addison's disease. Among the problems therefore awaiting solution at the hands of the pathologist are the extent and nature of the suprarenal disease necessary for the development of symptoms, on the one hand, and the ability of other organs to replace the function of the suprarenal bodies—whatever this may be—on the other.

Occasionally the suprarenal bodies fail to attain their normal degree of development; rarely they are entirely wanting. These conditions are usually associated with other developmental deficiencies, more especially anencephaly and hemicephaly; but as a rule they are not attended with symptoms of Addison's disease.

Hansemann, in *Berliner klinische Wochenschrift*, 1896, No. 296, has reported a case of Addison's disease in which the essential lesion consisted in what was believed to be aplasia of the cortex of the suprarenal bodies. The patient was a man, thirty years old, who presented profound weakness, in addition to impaired nutrition and slight jaundice. He had conspicuously dark hair and almost black irides, so that the swarthiness of his complexion was not especially noticeable. The scrotum and the mammillary areolæ, however, presented distinct pigmentation; so also did some old scratch-marks and the remains of former acne-pustules. The palate too presented a line and a spot of discoloration. The patient grew weaker and weaker and in a short time succumbed. Upon *post-mortem* examination the heart was found to be in a state of brown atrophy. At the apex of the left lung was a small slate-colored cicatrix, together with several small cheesy areas. In the intestines the follicles were swollen and the mucosa swollen and reddened in spots, with a number of hemorrhages. The suprarenal bodies were adherent to the surrounding structures. In their superficial extent they were of about normal size; the right was perhaps undersized. Conspicuous, however, was the reduction in thickness. On section no trace of cortex could be found. The whole gland was represented by reticular structure, containing large cells with pigment. In places a slight degree of small-cell infiltration was visible. Nowhere was there any considerable new formation of fibrous tissue and no noteworthy alterations were detected in the nervous system.

THE EVOLUTION OF BELLEVUE HOSPITAL.

BELLEVUE HOSPITAL, as the great charity hospital of this city, has had a very unique history. In reviewing its development from an almshouse to one of the most reputable public institutions, it is held by good authority that this hospital illustrates the method of properly governing these charities, of which there is a large number in this country. As a rule, they are under the exclusive control of the almshouse authorities of the counties, and hence are subjected to the pernicious influences of the lowest grade of partisan politics. The question which is agitating the

profession in many localities is as to the proper measures to be adopted to rescue these charities from their present degraded condition and place them on a secure basis for future proper development.

A brief notice of the progress of Bellevue Hospital, which has passed through every stage of evolution, from the most disreputable poorhouse to a hospital of the first rank as regards its general government and the character of its medical service, may prove useful.

This hospital was opened in 1816, eighty years ago, as the great Charity Hospital of the city. For ten years it was part of the almshouse proper, and under the same management. During this period the hospital became so notorious for its vices and abuses that its very name was a "terror" among the poor. From 1826 to 1847, a resident physician was the nominal head of the hospital, but as he was simply the agent of the governing board, few reforms were effected. In 1847, the medical profession undertook the task of reorganizing the medical service, and succeeded in having a medical board, composed of competent physicians, appointed, with enlarged powers over the management. This was the beginning of real improvements in the hospital. The resident physician was removed, competitive examination of the resident staff was instituted. The introduction of competent medical men into the management of the hospital was of immediate benefit, for it led to the proper care of patients on the part of the resident staff, more exactness in the administration of remedies, strict attention to the sanitary condition of the entire building and grounds, and a careful oversight of all the details of nursing, feeding, and general discipline. The entire *morale* of the institution was changed, and in every part improvements were noticed. The advance of the hospital from that date to the present, though gradual, has been continuous and uninterrupted.

In the period 1850–1860, clinical instruction was given by the visiting staff, and students were attracted in such increasing numbers that in the decade 1860–1870 the hospital became the great center of clinical teaching of the medical schools. It brought into the visiting staff a still higher order of medical men, and into the resident staff a better class of recent graduates. It concentrated upon the individual patient far more thought and study, both in the discovery of the nature of the disease and in exactness in the employment of remedies. Finally, it introduced into all branches of the service that degree of system and discipline so essential to successful hospital management. In 1872 a training school was established, which revolutionized the ward management and perfected this branch of the service.

The last stage of progress in the evolution of the hospital was the more intimate relation of the medical schools to the management. The service was divided so that each of the colleges had exclusive control of a division, and one division was assigned to members of the staff unconnected with the schools. With this change, the highest order of medical service was secured. The visiting medical staff was composed of the most advanced teachers in their several branches, while the positions in the resident staff became the prizes in the schools most sought after by the students. Thus organized and managed, Bellevue Hospital, according to the report of the Committee on Hospitals of the State Board of Charities, is regarded as a model of excellence.

It will be possible for but few of the charity hospitals of the country to adopt the full scheme of government above outlined, but they can generally be placed under medical boards composed of competent practitioners of the locality. The first step in reform consists in the removal of the medical service of the hospital from the control of the local poor authority to that of the profession. The next step will be the introduction of the trained nurse, which will at once relieve the ward of its hereditary almshouse abuses and scandals. But where the hospital can be utilized for teaching, the crowning act of reform will be the subordination of the hospital management to the elevating and disciplinary influences of the medical school.

A CRITICAL RESUME OF RECENT PROGRESS IN DERMATOLOGY.

PEMPHIGUS.

A GREAT deal of attention has been given of late to the subject of pemphigus, which has always been a fruitful source of discussion. In

time past every bullous eruption was called a pemphigus, qualified by some adjective. At one time authorities described nearly one hundred different forms of this disease. A bulla is one of of the primary lesions of the skin and may form under many conditions and in a number of diseases. Happily the present tendency is to the simplification, as far as may be, of dermatological disease classifications, and it is probable that, in course of time, the number of forms of pemphigus will be greatly reduced, much to the benefit of the student of dermatology. In the fifth meeting of the Deutsche Dermatologische Gesellschaft, pemphigus was one of the subjects for discussion. Kaposi, who is always conservative, upheld the view that pemphigus was a definite disease, essentially malignant, and chronic, with a death rate of probably over forty per cent. Its victims, he said, died of amyloid degeneration of the organs, parenchymatous alterations of the heart muscle, diarrhea, and pneumonia. One form of pemphigus may change into another form, showing that all forms are but parts of one disease. He saw no reason for the establishment of such diseases as dermatitis herpetiformis, and pemphigus vegetans. He had never seen a case that he was willing to recognize as dermatitis herpetiformis, as separate from pemphigus, and would regard that disease as described by Duhring as including a number of well-recognized diseases, such as urticaria papulo-bullosa, annularis, gyrata; lichen urticatus, and the bullous form of erythema multiforme.

Rosenthal, who followed Kaposi in the discussion, excluded from pemphigus a number of cases that had been included under it, such as all accidentally bullous affections, as urticaria; all bullous dermatitides; the bullous forms of syphilis and leprosy; pemphigus hystericus; erythema bullosa; hydroa vacciniforme and varioliforme; epidermolysis bullosa; dermatitis herpetiformis; herpes gestationis and impetigo herpetiformis. He believed in the identity of dermatitis herpetiformis. He regarded pemphigus foliaceus and pemphigus vegetans as forms of pemphigus vulgaris, and pemphigus acutus as an infectious disease ending fatally in most cases. Pemphigus vulgaris, he held, was a subacute or chronic disease, exceedingly rebellious to treatment, presenting single-chambered bullæ, whose seat is below the corneous layer of the skin. Its prognosis was favorable, if of the subacute variety, bad if of the chronic variety.

Schwimmer recognized the identity of dermititis herpetiformis. Neumann, on the other hand, did not recognize it, but upheld that pemphigus vegetans was a disease sui generis, which was natural, as he was the father of the name.

At the same meeting Eppinger of Grätz, read a paper on the pathological anatomy of pemphigus, in which he stated that his investigations led him to believe that the disease was due to the development of toxins, which first affected the peripheral part of the cutaneous nerves, and later the central nervous system. Through alterations in the terminal ends of the nerves alterations in the skin took place. At first there were changes in the blood-vessels with serous exudation or even hemorrhages.

The whole discussion was a most interesting one, and cannot fail of being helpful. In the present unsettled state of our knowledge it seems to me best to regard as pemphigus only those cases marked by the appearance of bullæ with little or no erythematous halo, that run a subacute or chronic course, and tend to deteriorate the general condition of the patient. Experience of dermatologists in this country certainly upholds our distinguished countryman in establishing dermatitis herpetiformis as a separate disease.

Many of the cases reported as acute pemphigus are certainly only instances of what we here recognize as the bullous form of impetigo contagiosa. Pernet and Bulloch (*Brit. Journ. Dermat.*, 1896, viii, p. 157), report a case of acute pemphigus that certainly is not contagious impetigo. It occurred in a butcher, and apparently originated at the site of a scar, and was probably due to a specific micro-organism. Fifteen weeks after the injury a bulla formed at its site, and nine days later a general eruption of bullæ occurred. Within seventeen days the man was dead. The authors have collected seven other cases of a general bullous eruption following, or presumably following injuries, all being butchers, in six of which death soon occurred. The period elapsing between the time of the injury and the appearance of the bullæ varied from five weeks to three months.

By the French school skin diseases have always been regarded as local manifestations of general disease conditions, while German dermatologists, notably those of the Vienna school, have taught for years the purely local origin of most dermatoses. Within the past three months two papers have appeared, one in France and one in this country, treating of dermatoses occurring in connection with general diseases. Frèche, of Bordeaux (*Journ. mal. cutan.*, 1896, viii, p. 4), discusses the *eruptions of hysteria*. These he finds to be dermographism, erythema, ecchymoses, and bloody sweats, chronic urticaria, and eczema. All these diseases, of course, occur also in non-hysterical subjects, and have no special marks to distinguish them when in hysterical ones. He believes that pemphigus and gangrene are more frequent in hysterical than in non-hysterical subjects, the latter indeed being seen in them especially. The description he gives of the former would lead me to think that his cases were of the disease we call dermatitis herpetiformis, because of the perodicity of its outbreaks, its patchy character, and the itching, smarting, and burning that attends it. All these symptoms are characteristic of Duhring's disease. His gangrene, he says, has been described by Kaposi as zoster gangrenosus, and by Renault as urticaria gangreneuse. In it a red, white, or anemic lesion, slightly raised above the surrounding skin appears at some part of the surface of the body, and shortly after another patch will develop at a distant part. The lesion turns blue, then black, breaks down and forms an eschar with a more or less suppurating line of demarcation. After the fall of the eschar a granulating ulcer is left that sometimes heals readily, sometimes only after a long time, and leaves a kelodal scar. The initial lesion may be a bulla, which becomes umbilicated, black, and gangrenous. The disease is always attended with pain, burning, or smarting, which disappear when the lesion forms.

The other paper is by Morrow of New York, and is a very complete study of diabetic eruptions. (*Med. Rec.*, 1896, xlix, p. 508). He divides his paper into two parts. The first treats of those diseases that are symptomatic of diabetes, namely: certain functional diseases of the skin as anidrosis, asteatosis, hyperidrosis, puritus, erythema, eczema, balano-posthitis, phimosis, furuncles, carbuncles, gangrene, and xanthoma diabeticorum. The second part of his paper deals with those diseases that occur incidentally and with comparative frequence in diabetes, and show a tendency to become better and worse with the fluctuations of the sugar in the urine. These are acne cachecticorum, chronic papular urticaria, impetiginous and lichenoid eruptions, psoriasis, dermatitis herpetiformis, mal perforant, erysipelas, and dermatitis diabetica papillomatosa. It will be observed that in both of these groups of dermatoses occurring in general diseases we have a bullous eruption, which the Frenchman calls pemphigus, but which the American recognizes as dermatitis herpetiformis. This is of special interest, taken in connection with the discussion noticed before. It is by such studies we may at last succeed in answering the question, What do we understand by pemphigus?

George Thomas Jackson, M.D.

ECHOES AND NEWS.

The next annual meeting of the Medical Society of New Jersey will be held in the Hotel Brunswick, Asbury Park, Tuesday and Wednesday, June 23 and 24, 1896, commencing at 11 o'clock A.M. on Tuesday.

At the annual meeting of the Washington State Medical Society, held in Tacoma, May 19th and 20th, Dr. R. L. Thomson of Spokane, was elected president, and Dr. J. M. Semple, of Medical Lake, secretary. The next meeting will be held in Spokane, May, 1897.

The silver lancet case and lancets, formerly used by Jenner and bearing his name, have been presented to the Royal College of Surgeons, to be placed among the other Jenner relics in the college museum.

The next meeting of British Medical Association will convene at Carlisle on July 28th and continue four days. The address in Medicine is to be delivered by Sir Dyce Duckworth, M.D., LL.D., and that in surgery by Roderick Maclaren, M.D.

At the special request of Coroner Hoeber of New York City, the police are instructed to leave untouched the effects and surroundings of any person dead from suicide, homicide, or suspected poisoning, until the coroner or his representative shall have seen the body. There already exists a law to this effect but it has been commonly disregarded.

A dispatch from London is authority for the statement that the Sultan is suffering from a tumor of the spine. He has refused operation for its removal because

his surgeons are unable to assure him that the procedure is not dangerous.

DR. HENLE, Professor of Anatomy at the University of Tubingen died on May 23d. He was one of the best known of modern anatomists and recognized as one of the best authorities upon the subject. He was, in the early part of his career, assistant to the physiologist Donder's in Holland, and was afterward elected professor in the Universities of Marburg, Rostock, Prague, and Tubingen respectively.

THE TWELFTH INTERNATIONAL MEDICAL CONGRESS is to have a special section devoted to the discussion of the alcohol question. This makes sixteen sections into which the Congress at Moscow is to be divided. It may be of interest to mention in this connection that a new method of treating alcoholism is being subjected to an extensive test in Bellevue Hospital, New York, at the present time. The plan is the result of the study of the subject by a member of the New York Academy of Medicine. It has been explained to the hospital authorities who are convinced of its harmlessness and possible value and have set aside one of the hospital wards for the purpose of giving it a thorough test. The method is not to be made public until it has proved itself efficacious.

AN idea prevalent among obstetricians that from the frequency of the fetal heart-beats the sex of the child can be foretold is now refuted. This oft-quoted theory seems to have had its origin in about fifty observations made by Frankenhauser, who stated that in male infants *in utero* the average rate was 124 a minute while in females it was 144. An observation including one thousand cases at full term at the Boston Lying-in Hospital has proven the disparity between the heart's action in male and female fetuses to be about 1½ beats. Knowledge obtained by counting the pulse rate is not reliable as data in determining the sex.

PROFESSOR PELLMANN of Bonn University, Germany, has made a special study of hereditary drunkenness. He has taken certain individual cases, a generation or two back, and has traced the careers of children, grandchildren, and great-grandchildren in all parts of the present German empire until he has been able to present tabulated biographies of the hundreds descended from some original drunkard. The last person whom Professor Pellmann has immortalized thus in medical literature is Frau Ada Jurke. She was born in 1740, and she was a drunkard, a thief, and a tramp for the last forty years of her life, which ended in 1800. Her descendants have numbered 834, of whom 709 have been traced in local records from youth to death by Professor Pellmann. Of the 709, he found 106 were born out of wedlock. There were 142 beggars, and 64 more who lived from charity. Of the women, 181 led disreputable lives. There were in this family 76 convicts, 7 of whom were sentenced for murder. In seventy-five years this one family rolled up a big bill of costs in almhouses, trial courts, prisons, and correctional institutions. Professor Pellman says this bill, which the authorities of Germany and therefore the taxpayers have paid, has been at least 5,000,000 marks, or about $1,250,000.

THE cheap restaurant started by the Clark Thread Company of Newark, for the benefit of its employees has been abandoned because the employees failed to patronize it. The restaurant was started last fall, and was run at a loss for seven or eight months. During the winter the patronage was encouraging, but when warm weather came the trade diminished. The object of the restaurant was to encourage the operatives, and the girls especially, to eat sustaining and wholesome food prepared in a scientific manner, but the young women resented the absence of crullers, doughnuts, and pie, and sneered at the nourishing stews, soups, etc. The prices were very low and the quality of the food was of the best, while there was considerable variety. The absence of pie and cake doomed the enterprise, however. Some practical instruction in physiology in our public schools might avail to correct such mistakes.

THE last calamity to befall Gloucester, England, is a raid upon it by the quacks. The *British Medical Journal* has the following note regarding the latest conditions at that place: "The isolation hospital continues quite full with 296 patients, in addition to whom a large number have still to be treated at their own homes. As is usual in such cases, the city has been visited by all sorts of 'professors' of the healing art, each of whom declares his own particular nostrum to be infallible, not only in curing but in preventing an attack of smallpox. Under the patronizing influence of the local daily paper which has for so many years done its best to discredit vaccination, the advocates of these panaceas have been allowed free scope for making their claims known to the public in its news and correspondence columns. It need, therefore, be no subject for surprise that the hopes thus unscrupulously held out have been grasped at by the unfortunate victims of the disease and their friends, and that the noble army of 'quacks' is doing a brisk trade just now in the city within the precincts of whose cathedral the statue of Jenner looks down on this turmoil of noisy pretenders with the calm confidence of true science."

CHIEF SURGEON DR. J. F. VALENTINE, of the Long Island Railroad, is engaged in organizing a hospital department for the employees of that corporation on the plan of co-operative support, that is so well advanced among certain of the large Western lines. The Atchison, Topeka and Santa Fé Company furnishes hospitals at various towns along the line of the road. The expenses of maintenance are secured by assessments of from 25 to 50 cents a month on each employee, the amount depending on the salary received. The payment of this assessment insures the best of treatment in case of accident or sickness. The Plant System, at the South, has adopted an additional feature, namely, the hospital-car, developed under the direction of Dr. F. H. Caldwell, chief surgeon of the Plant System. These hospital-cars are scattered along the road at division points. In case

of an accident one of these cars is dispatched to the scene at once, and the wounded are cared for properly and immediately. An operating room in the car is fitted with a glass-topped table and all the appliances for performing asceptic operations. There is a consultation room and a larger apartment, fitted with cots and hammocks, in which the injured may be conveyed safely and comfortably to the railway hospitals. It is proposed to have these hospital-cars so located that one can be sent to any point on the road within two hours. A supply of stretchers is aboard each of the hospital-cars, on which the wounded may be removed from the wreck. Each car will have accommodations for more than a dozen patients. The intention of Dr. Caldwell is to use the hospital-cars chiefly to transport the wounded to hospitals. The operating room will be used only when the indications are in favor of immediate operation.

THE following is offered by the *Journal of the American Medical Association* as evidence of "a recruit for Achilles Rose." A new style of prescription writing is recommended by Dr. Loeffler in the *Aerzt. Korrespondenzblatt*. The author calls attention to the fact that in prescribing the newer remedies, the names of most of which are familiar to the general public, the customary writing of prescriptions in the Latin language does not protect the physician from inconvenient criticisms of laymen, so that it often would seem advisable to adopt a style less intelligible to most persons. To this end Dr. Loeffler has used for sometime the Greek alphabet though still retaining the Latin nomenclature, and in all the apothecary shops of Dresden his prescriptions are readily understood, *e.g.*, he prescribes antipyrin as follows:

℞ ἀντιπυριν 1.0
Δ. Ταλ. Δωσ. Νω. χ.
Σ. Daily, etc.

WESTERN MEDICAL REVIEW is the name of a new monthly medical journal, edited by George H. Simmons, M.D., and published in Lincoln, Neb. We are in receipt of Nos. 1 and 2. They are fresh and breezy, first-class, clean, and every way up-to-date. We welcome the *Western Review* to the ranks, and predict for it a most successful career, and a future full of usefulness to the profession of Nebraska and the West.

THE diagrams furnished by the Chicago Board of Health with the March, April, and May monthly reports show, in graphic manner, the sanitary quality of the water and the average daily deaths from the diseases affected thereby for a period of twenty-four weeks—from the week ended December 21, 1895, to the week ended May 30, 1896, inclusive, Examination of these diagrams discloses three periods of several successive weeks each, to-wit: first, from December 21 to January 25—six weeks; second, from February 22 to April 2—seven weeks; third, from April 11 to May 30—eight weeks. During these periods the deaths from the acute intestinal diseases—also shown on the diagrams—were 206, 137, and 258, respectively. The water supply was "suspicious" or "bad" during the first and third periods, with an aggregate of 464 deaths, or a daily average for the fourteen weeks of 4.7. The water was "usable" or "good" during the intermediate period of seven weeks with an aggregate of 137 deaths, or a daily average of 2.8. The higher death rate of the first and third periods can be attributed to no other cause than polluted water. Applying to the entire year the figures of the twenty-four weeks covered by the diagrams—which is certainly a sufficiently long period to generalize from—we should have with a good sanitary quality of water, 365 days x 2.8 deaths = 1022 total deaths; with a bad sanitary quality of water, 365 days x 4.7 deaths = 1715 total deaths. Excess of deaths due to polluted water, 693, at $5000 each = $3,465,000. This sum represents the interest at five per cent. on a capital of $70,000,000. How much of this amount would be required to complete the drainage channel, build intercepting sewers, and insure a pure water supply the year round?

IT is reported by Dr. Audry, of the Toulouse Faculty, that by the action of radiant heat from a thermo-cautery, which is brought near but not in contact with a soft chancre, the process is converted into a simple ulcer. The usual application of a cautery is of course followed by an eschar that slowly separates, whereas the method of Audry avoids this inconvenience and is quite as effective.

THE death of Sir George Johnson, M.D., F.R.S., Physician Extraordinary to Her Majesty the Queen, occurred on June 3d, after a brief illness.

CORRESPONDENCE.

THE NEW URETHROSCOPE—DR. HAWKINS' REPLY.

To the Editor of THE MEDICAL NEWS:

DEAR SIR: I have always regarded the name of Otis with the most sublime respect, and deeply regret the fact that I am constrained to differ with one bearing that great name, and am liberal enough to acknowledge a mistake when I have made it. In regard to the criticisms of Dr. W. K. Otis of my Urethroscope, if I have been guilty or claiming the results of some other person for myself I regret it and it is unintentional, but I think if Dr. Otis will kindly reread the description of the instrument he will find that it encroaches on no one's previously acquired territory.

I may have been hasty in passing my opinion on Dr. Otis' "Perfected" Urethroscope, as it is possible that that there may be a difference in the instrument as made by me and the one made under his direct supervision. The instrument which I used was made from the description published by Dr. Otis in *The New York Medical Journal* of December 17, 1892. After using this instrument for a while I hit upon the idea of applying the principle of the ophthalmoscope to the urethroscope, with the result described in THE MEDICAL NEWS of May 23d. I was not aware that an instrument of this description had ever been made, and if the original instrument of Dr. Otis, as shown in Culver & Hayden's Manual of Venereal Diseases, is reproduced in my instrument I would cheerfully apologize to the doctor. But I am unable to see the similarity, as I use a mirror with a perfor-

ated center as is used on the ophthalmoscope, while that on the Otis instrument is a solid mirror, as on the Leiter, set low enough for the returning rays from the tube to strike the operator's eye. The doctor has observed a technicality in my wording of the sentence regarding the quantity of light I claimed was thrown down the tube with my instrument. The mirror used on my instrument is about the same size as that on the Leiter, 1½ inch. With my instrument, on actual measurement, a cone of rays whose base, on the face of the mirror, is about a half inch in diameter, is all the light that is actually used, the remainder being spread out upon the face of the plate on the Klotz tube. Now with my instrument the light is gathered from *all around* the central perforation *in the shape of a cone*, whose radius at the base is one-fourth inch. With the Leiter plan, using the mirror set below the path of the rays, the light is gathered from *less than one-half as much mirror surface*. It is then only reasonable that with the same lamp more rays will be thrown down the tube than with the Leiter. I have used in these experiments a Klotz tube, No. 26 F., 4½ inches long. I use a four-volt Edison electric lamp of one candle-power and get a light far superior to that obtained with the Leiter instrument. This last assertion has been verified by other observers with my urethroscope.

I do not deny that a bull's-eye condenser will throw a powerful light; such a statement would be ridiculous, but the trouble I experienced with the instrument made from Dr. Otis' description of his "Perfected" Urethroscope was to intercept the return rays as the condensing apparatus obstructed the path. It is, therefore, necessary to lower the condenser, as with the Leiter instrument, and look over the top of it.

Anyone, not inclined to quibble, can at a glance see the difference between my instrument and that of Desormeaux, which was invented before the days of the practical application of the electric light. The U. S. Patent Office recognizes and issues letters patent on "new combinations of old parts, whether relating to material objects or to processes."

I stated in my paper that a portion of the mirror in the Leiter instrument was removed to complete the axis of vision. My wording might have been clearer, the meaning I wished to convey being that set forth above—the removal of a portion of the mirror below the path of the rays in order to allow the operator to look over the instrument, caused *not a "little more than one-half* of the light thrown in the direction of the mirror" *to be wasted*, but *all except those rays from the upper part of the mirror*, a little more than a quarter by half an inch in area, as stated above.

That the principle of this instrument is correct is shown by the exclusive use of the principle by the ophthalmologist, and the almost exclusive use of it by the rhinologist, laryngologist, otologist, and many genito-urinary surgeons who do not possess a urethroscope—*all* using a mirror *with the rays of light passing through the central perforation.*

JOHN A. HAWKINS, M.D.
105 JACKSON STREET, ALLEGHENY, PA.
JUNE 9, 1896.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

General Meeting, June 4, 1896.

JOSEPH D. BRYANT, M.D., President.

DIPHTHERIA ANTITOXIN.

THE discussion of this subject was begun at a regular meeting of the Academy, May 21st, by JOSEPH E. WINTERS, M.D., who read a paper upon

CLINICAL OBSERVATIONS UPON THE USE OF ANTITOXIN IN DIPHTHERIA; AND A REPORT OF A PERSONAL INVESTIGATION OF THIS TREATMENT IN THE PRINCIPAL FEVER HOSPITALS OF EUROPE, DURING THE SUMMER OF 1895. (SEE PAGE 685.)

The meeting then adjourned to June 4th. The discussion was continued by P. H. ERNST, M.D., of New York, who read a paper upon

EXPERIENCES WITH THE ANTITOXIN.

He reported seventy-seven cases of diphtheria treated by him, for the most part in dispensary practice, since May, 1895. Of these cases, twelve had been treated with antitoxin, eight of them being considered severe and four mild. Of this series, seven died. Of the sixty-five treated without antitoxin, forty-two were considered to be severe. Eleven of the cases were intubated. The number of deaths in this second series was eleven. Dr. Ernst said that he had at first expected much from the antitoxin, but finding that it did not appear to have the slightest favorable influence, and that convalescence after its use was especially tedious, he abandoned the treatment.

W. L. STOWELL, M.D., presented the next paper, upon

DIPHTHERIA WITH AND WITHOUT ANTITOXIN. (SEE PAGE 694.)

WILLIAM H. THOMSON, M.D., of New York, opened the general discussion by calling attention to the fact that in estimating the value of a method of treatment for any infectious disease, there were certain unavoidable and important sources of error. For instance, the diagnosis was often a matter of uncertainty; the important influence of individual "soil" must be taken into account, and the virulence of the pathogenic microbes themselves varied very greatly at different times. The opponents of antitoxin had assumed, though most illogically, that this complex antitoxin serum must exert a specific effort, comparable to the action of a chemical antidote, and also that the occurrence of failures with this remedy was proof that it was useless. If such an argument were correct, we would be compelled by the same process of reasoning to conclude that mercury is worthless in the treatment of syphilis, and quinin of no value for the cure of malaria. To decide upon the value of this treatment, reports of many thousand cases must be submitted from many different parts of the world, so as to eliminate local sources of error. Such evidence, he thought, was already at hand. Dr. Thomson then read extracts from hospital reports in various parts of the world, regarding the effect of antitoxin in the treatment of diphtheria. Out of eighty-five

such hospital reports, there had been collected the results of the treatment in 9893 cases of diphtheria, viz., 1820 deaths, or a mortality of 18.3 per cent. In addition to this, fifty-three of the hospitals furnished definite comparisons with the death-rate prior to the introduction of diphtheria antitoxin, which was found to have been 44.3 per cent. It was evident, therefore, that the death-rate in the hospitals had been reduced at least fifty per cent. by the antitoxin treatment. The speaker also presented reports from private practice, aggregating 3760 cases of diphtheria treated with antitoxin, with 296 deaths, or a mortality of 7.8 per cent. Adding together the hospital and private cases, one obtained a total of 13,653 cases, with a mortality of 15.5 per cent. This mortality, Dr. Thomson said, showed that diphtheria antitoxin was not a "specific" in the sense in which Dr. Winters used this term, *i.e.*, a remedy which should give a uniform percentage of recovery all over the world, and should be invariably successful. It would not do to report an occasional failure from antitoxin as an argument against the value of the remedy. He believed that antitoxin had been already proved to be a remedy of great efficacy, and he looked upon the introduction of this new method of treatment as one of the great achievements of this century.

GEORGE L. PEABODY, M.D., of New York, said that it was not fair to argue that because a remedy did not reduce the mortality to the same extent everywhere, that therefore the remedy is useless. No remedy of modern times could stand such a test as that. Statistics of any treatment were largely affected by the fidelity and zeal with which that treatment was carried out. For example, Brandt had collected records of 19,000 cases of typhoid fever treated by his cold-bath method, by all classes of physicians, with a mortality of 20 per cent., whereas in 800 cases treated by the same method, but only by those having faith in the treatment, the mortality was 8 per cent.

Referring to the meeting of two weeks ago, he said that we had been told at that time that a number of cases had died shortly after the administration of antitoxin, and the inference had been drawn that it was because of the administration of this remedy; but we had not been given sufficient details regarding these cases to enable us to judge intelligently as to the cause of death. It was true that in some instances the use of the immunizing serum had failed to prevent the development of diphtheria, but in these cases might it not be reasonable to suppose that the disease had been already in the system, but inactive? Much stress had been laid upon the fact that the physicians who had witnessed the use of antitoxin in the hospitals, had refused to submit themselves to this treatment. Such an argument was not a particularly strong one, but to offset this he would say that last winter he had received a large dose of antitoxin, with no ill effect other than the production of a slight urticaria around the site of the puncture. Some of the serious consequences reported after the use of antitoxin, were probably due to impurities in the antitoxin, but this was rather an argument against these impurities than against the antitoxin, and moreover he had been informed that some of these impurities, at least, could be readily detected, so that this possible source of danger was largely preventable. His experience with the remedy had impressed him with the important part played by individual susceptibility. For example, he had personally injected three patients at the same time, with the same antitoxin, using the same syringe. One of these individuals, an adult, developed a severe urticaria with joint pains, while the other two, an adult and a child, showed no unpleasant effect from the treatment. At the previous meeting he had been led to believe by the speaker of that evening, that it was our duty to listen to and accept all evidence against antitoxin, and close our ears to all reports that were favorable to the remedy.

J. J. KINNION, M.D., of the Marine Hospital Service, sent through Dr. A. A. Smith, a communication, which was read by the secretary. In it, he said, that for the past five years the Marine Hospital Service had been making a collective investigation regarding diphtheria, and had in this way collected records of 131,620 cases of diphtheria and croup, occurring from 1891 to 1894, with 51,820 deaths, or a mortality of 39 per cent. These reports came from 109 cities, and in 1895 the same cities reported 45,690 cases with 11,640 deaths, or a mortality of 25 per cent. The reports indicated that where antitoxin had been used most freely, the death rate had been most markedly reduced. The reports also showed that 2936 cases had been treated without antitoxin, with 1010 deaths, or a mortality of 41 per cent. Of 2400 children who had received the serum for immunizing purposes, only 19 cases of mild diphtheria had developed within a few days, and no ill effects had been noted from the use of the serum.

JOHN W. BRANNAN, M.D., of New York, in discussion presented

A CRITICAL ANALYSIS OF DR. WINTER'S CLINICAL OBSERVATIONS ON THE ANTITOXIN TREATMENT OF DIPHTHERIA. (SEE PAGE 691.)

H. W. BERG, M.D., of New York, said that the probable explanation of the greater frequency of bronchopneumonia as a complication of the cases of diphtheria which had been treated by antitoxin, was that this remedy kept a larger proportion alive for a sufficient length of time to allow of the development of the pneumonia. The much greater frequency of this complication in hospital practice had been noted, and was probably explicable on the theory that it was due to a streptococcus infection. He would explain Dr. Ernst's unfavorable experience with antitoxin, by the fact that his cases had been seen in dispensary practice, and consequently at a late stage of the disease, From the description given by Dr. Ernst, it would seem that these cases had been of a severe type. Dr. Winters had certainly been most industrious in the collection of his facts, but he had unfortunately drawn from them very illogical conclusions. His great argument against antitoxin was that its administration had been followed at times by sudden death. If this were a valid argument, one would expect such a result to be much more common, to say nothing of the fact that sudden deaths were by no means unheard of before the advent of this new treatment. In his opinion, it was incumbent upon the opponents of the antitoxin treatment to prove

that the remarkable results obtained in the laboratory with this remedy cannot be reproduced in the treatment of the human subject. Personally, he had been profoundly impressed with the results of the treatment in his private practice, and he looked upon antitoxin as the most remarkable remedy he had ever used.

A. CAILLÉ, M.D., of New York, said that he had intended to prove that Dr. Winter's communication was devoid of any scientific value, but as that had already been done he desired only to refer to the results of the collective investigation instituted by the American Pediatric Society, and only just now brought to a conclusion. This report has been most carefully prepared, and included 6000 cases from private practice, occurring in all parts of the United States and Canada. In every instance, the diagnosis had been confirmed by a bacteriological examination. The report showed most conclusively the correctness of Behring's claim, that the mortality in diphtheria could be reduced by the use of antitoxin to five per cent. or less. Personally, he had obtained most gratifying results from its use in the treatment of diphtheritic croup. Before using it his death rate in these cases had been about seventy per cent., but recently he had had the pleasure of witnessing the recovery of ten consecutive cases under the antitoxin treatment. History showed that opposition was one of the accompaniments of the evolution of scientific medicine. He would say most emphatically that in his opinion antitoxin had come to stay.

HAROLD C. ERNST, M.D., of Boston, said that experience had emphasized the importance of using a reliable preparation of the antitoxin, and of always taking it from a freshly opened bottle, There had been reported to the Boston Board of Health 1164 cases of diphtheria, which had been treated with antitoxin, Of this number 983 were treated in the Boston City Hospital, with a mortality of 15.6 per cent. For years past the mortality from diphtheria in that hospital had been over 40 per cent. Of the 181 cases from private practice fifteen died, or a mortality of 8.2 per cent. The records showed that the general mortality in Boston for the twenty years past had never been less than 26.5 per cent. until last year, when it dropped to 14.48 per cent. He had also received reports of 346 cases in which the serum had been used for immunizing purposes, and in not a single instance had there been any evidence of paralysis, nephritis, or indeed of any serious consequence. This was good proof of the harmlessness of the antitoxin serum.

GEORGE MCNAUGHTON, M.D., of Brooklyn, said that when he had reported last year the treatment of nineteen cases of laryngeal diphtheria with seventeen recoveries, Dr. Winter's rejoinder had been that that meant nothing. He could now report a total of eighty-nine cases of laryngeal diphtheria treated with the aid of antitoxin, with only thirty deaths. All of these cases had been seen in private consultation practice, from which it was fair to infer that most of them were of a severe type. All but five of the cases had been intubated. On searching his records for purposes of comparison he had found that of the seventy-two cases treated just before the introduction of antitoxin forty-eight had died, whereas of the first seventy-two cases treated with antitoxin only twenty-four had died. He was convinced that this indicated that antitoxin had a definite value.

WILLIAM H. PARK, M.D., of New York, said that one of the strongest points in the statistical argument in favor of antitoxin was that by the use of this remedy the death-rate from diphtheria had been reduced, not merely in one or two localities, but all over the world. Of the 2000 cases immunized by the New York City Board of Health, only two had shown any complications worthy of note, and in only six had the disease developed between the second and thirtieth day. He had spent much time in observing the same cases in the Willard Parker Hospital, as had Dr. Winters, yet he was forced to agree with Dr. Brannan that the clinical picture of these cases, as portrayed by Dr. Winters, was not that which he had seen. Moreover, Dr. Winters had shown an evident lack of care in collecting his statistics, for he had referred to eight consecutive recoveries from laryngeal diphtheria having taken place in the Hospital in December, whereas the Hospital records showed that, as a matter of fact, all the laryngeal cases in this month had succumbed to the disease.

H. HERALD, M.D., of Newark, said that just prior to January 1, 1895, the time of the adoption by the Newark Board of Health of the system of making bacteriological examinations to establish the diagnosis of diphtheria, the mortality from diphtheria in that city had been about thirty-five per cent. After July 20, 1895, the Board had supplied its own antitoxin, and from that date to May 1, 1896, 1039 cases of diphtheria had been reported, with 243 deaths, or a mortality of 23.1 per cent. Of the 653 cases in which antitoxin was used there were ninety deaths, or 13.5 per cent., while in 386 cases in which it was not used, there were 153 deaths, or a mortality of 39.6 per cent. In the Newark City Hospital, before the antitoxin treatment, the mortality from diphtheria had been forty-two per cent.; since its introduction, 16.4 per cent.

HENRY F. KOESTER, M.D., of New York, said that from February 28, 1895, to January 1, 1896, he had used antitoxin in 200 cases in private practice, with 40 deaths, or a mortality of 20 per cent. Of these 200, 36 were laryngeal, and the mortality in this class was 27.7 per cent. Of the 355 cases in which he had employed the serum for immunizing purposes, 4 had developed the disease within twenty-four hours. He had never seen any serious results from the treatment, and now preferred to give an initial injection of as much as 2000 units.

J. MILTON MABBOTT, M.D., of New York, said that so far as he had been able to learn, there had been no very great diminution in the actual number of deaths from diphtheria, and in the few cases in which he had known it to be used in private practice, the disease was of such a mild type that no reliable inferences as to the curative value of the serum could be drawn. Certainly, many cases which did not present the clinical picture of diphtheria were nevertheless pronounced to be such by the bacteriologists of the Board of Health.

JOSEPH E. WINTERS, M.D., of New York, in closing the discussion, said that Dr. H. C. Ernst, in contrasting the death-rates in Boston for the last two or three years,

had neglected to state that there had been 112 more deaths in Boston in 1895 than in 1894. This same criticism applied to almost all the reports received, and it could not be too strongly emphasized that the percentage death-rate was absolutely worthless unless accompanied by the total number of cases and the total number of deaths. A good example of the wide variations in the type of the disease was to be found in the fact that in one year, in Philadelphia, 350 deaths from diphtheria were reported, whereas, three years later, there were over 1400 deaths. In the Willard Parker Hospital, the mortality in the intubated cases since the introductiou of antitoxin was about 68 per cent. In the Municipal Hospital, Philadelphia, the mortality in this class of cases, in 1895, without antitoxin, was 56.3 per cent.

In reply to Dr. Brannan, he would say that, in citing illustrative cases, he had not limited himself to the first few months of 1895 or 1896, but had taken the cases from the entire record, and in presenting them had given the dates of their admission. His first impression of the antitoxin treatment had been obtained from the observation of a case in the Willard Parker Hospital, in the fall of 1894. The patient was a robust young physician, affected with a severe, but uncomplicated diphtheria, yet, in spite of the antitoxin, the case had terminated fatally in two weeks and one day, and apparently without the antitoxin having exerted the slightest favorable influence upon the course of the disease. That same autumn, only five cases had received this treatment at the Hospital. Of this number, four died, and the fifth only recovered after an exceptionally prolonged convalescence.

These facts had impressed him so deeply that he had sought the counsel of the late Dr. A. L. Loomis, and had been advised by him to make public his adverse views regarding antitoxin. He had, however, shrunk from so doing at that time, lest his conclusions might be premature, and he might in this way deprive others of whatever benefit there might be in the new treatment. He had been accused of being prejudiced. That was an awful accusation to make in regard to such a dreadful disease as diphtheria, and those who knew him best were aware that he could not have been brought into the position in which he found himself to-night, had he not been profoundly impressed with the dangerous nature of this so-called remedy. If he could believe that it was harmless, as well as useless, he would never have raised his voice against it. As it was, he felt that in time every member of the Academy would be forced by his own convictions to feel as he did at present on this subject.

ANNOUNCEMENT.

VACANCIES IN THE MEDICAL CORPS OF THE U. S. ARMY.

THERE are at present three vacancies in the medical corps of the United States army, and it is expected that at least three more will occur during the present year. As usual, an Army Medical Board will meet in Washington early in October for the examination of candidates. The requirements for admission to the medical corps are stated in a circular issued by the surgeon-general of the army, dated May 21, 1896, and approved by the Secretary of War, as follows:

"Permission to appear before the Board is obtained by letter to the Secretary of War, which must be in the handwriting of the applicant, giving the date and place of his birth, and the place and State of which he is a permanent resident, and inclosing certificates, based on personal acquaintance, from at least two reputab' persons as to his citizenship, character, and habits. The candidate mus. be a citizen of the United States, between twenty- twenty-nine years old, of sound health and good char and a graduate of some regular medical college, in dence of which his diploma will be submitted to th board. The scope of the examination will include the morals, habits, physical and mental qualifications of the candidate, and his general aptitude for service; and the Board will report unfavorably should it have a reasonable doubt of his efficiency in any of these particulars.

"The physical examination comes first in order, and must be thorough. Candidates who fall below sixty-four inches in height will be rejected. Each candidate will also be required to certify 'that he labors under no mental or physical infirmity or disability which can interfere with the efficient discharge of any duty which may be required.' Errors of refraction, when not excessive, and not accompanied by ocular disease, and when correctable by appropriate glasses, are not causes for rejection.

"The mental examinations are conducted by both written and oral questions, upon:

"1. Elementary branches of a common school education, including arithmetic, the history and geography of the United States, physics, ancient and modern history, and general literature. Candidates claiming especial knowledge of the higher mathematics, ancient or modern languages, drawing, analytical chemistry, or branches of natural science, will be examined in those subjects as accomplishments and will receive due credit therefor according to their proficiency.

"2. Professional branches, including anatomy, physiology, chemistry, hygiene, pathology and bacteriology, therapeutics and materia medica, surgery, practice of medicine, obstetrics and the diseases of women and children.

"Examinations will also be conducted at the bedside in clinical medicine and surgery, and operations and demonstrations will be made by the candidates upon the cadaver.

"Hospital training and practical experience in the practice of medicine, surgery, and obstetrics are essential to candidates seeking admission to the medical corps of the army, who will be expected to present evidence that they have had at least one year's hospital experience or the equivalent of this in practice.

"To save unnecessary expense to candidates, those who desire it may have a preliminary physical examination and a mental examination in the 'elementary branches of a common school education,' by a medical officer of the army stationed most conveniently for this purpose, who will act under instructions from the Medical Examining Board."

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXVIII. NEW YORK, SATURDAY, JUNE 27, 1896. No. 26.

ORIGINAL ARTICLES.

NEPHROPTOSIS—MOVABLE KIDNEY.[1]

BY I. S. STONE, M.D.,
OF WASHINGTON, D. C.;
SURGEON TO COLUMBIA HOSPITAL FOR WOMEN.

By movable kidney, or nephroptosis, is meant a displacement downward of the organ, with more or less latitude of motion in any direction. Such a kidney is generally movable within its ordinary capsule or peritoneal investment, and cannot become a floating kidney which has a mesonephron and is a congenital malformation. The kidney is in some cases quite movable and yet adherent to its capsule, as will be found occasionally when operations are performed which develop this fact. A movable kidney will not always assume a position at the lowest point of a loose capsule, as we frequently experience difficulty in locating them when most wanted—as during a consultation. The erect position favors descent, however, and we can generally succeed in finding such a kidney below the ribs.

Some authors declare that a kidney must be displaced far below its normal site in order to be palpated, and that even this limited descent causes the well-known symptoms due to prolapse. It may be taken for granted that a kidney in its normal site in a thin subject can readily be felt or palpated over the lower half or third of its surface. The organ may descend to the pelvic brim, in fact often does, thus showing great mobility. Any change forward or downward of a kidney means displacement. To this, if mobility be added, we have the condition under consideration.

The writer has never seen a floating kidney, nor a movable kidney, whose lateral motion permitted it to reach beyond the median line. It is to the very movable cases only that the writer has given close attention, such as are supposed to need surgical treatment. The less movable cases are kept under the observation of the family physician, no operation being suggested save when positively and plainly indicated. Authors agree that many women who have neurasthenia, gastrointestinal atony, dyspepsia, etc., have nephroptosis. Some authors claim twenty-five per cent., and others even a higher rate for this class. There is but little truth in the claim that twenty-five per cent. of all women have this disease, if indeed it be a disease. It is true, however, that of the class mentioned above, from ten to twenty-five per cent. have some degree of mobility.

In this country, Edebohls of New York, and Johnston of Richmond, have the credit of first making a report of cases in number sufficient to test the advisibility, propriety, success, and permanence of operations looking toward a relief of this condition, as well as to cure the symptoms attributed to it. Dr. Osler has contributed interesting and indeed valuable clinical information, which may be found in his little book on abdominal tumors.

Frequency.—Edebohls says twenty-five per cent. of his female patients who have had pelvic disease have movable kidney. Other writers agree that a very large percentage of cases occur in persons apparently in good health. Lindner says one in six of the gynecological cases have movable kidney.

It is generally admitted that women are most frequently found to have movable kidney, although many observers have found it in men. It occurs in adults for the most part, between twenty and forty-five years of age. This period includes that period of a woman's life during which her diseases are watched and carefully studied by the obstetrician and gynecologist. Herein lies at least a possible explanation of the frequency at this period. Nephroptosis occurs often in thin subjects. The fat within the capsule has, to some extent, been absorbed. Obviously, fat subjects might have movable kidney, and the patient and physician be quite unaware of it.[1]

Pregnancy, pelvic disorders, and inflammations, abdominal tumors, absence of fat, have been

[1] Read before the Medical Society of the District of Columbia, Wednesday, March 18, 1896.

[1] The writer has never seen a movable kidney in a negress of dark color, and only once in a mulatto.

assigned as being closely related to the etiology of this disorder. The first case observed by the writer was relieved of symptoms due to the displacement during the latter months of pregnancy. It is highly improbable that tumors have much influence upon the mobility of a kidney, unless through pathological adhesions to the capsule. Neither does the writer think corset-wearing responsible for it. But we do find more cases occurring in women who have been the victims of pelvic disease, and according to some authors, of appendicitis. (Edebohls.) Most observers agree that the right kidney is most frequently misplaced on account of its position under the liver. The writer doubts this supposed influence of the liver.

Symptoms.—Anorexia has been present in most cases; actual vomiting in two cases. Pain is not a marked or characteristic symptom of movable kidney.[1] The only case observed by the writer in which pain actually existed had perinephritic disease. Other observers, however, mention severe pain as one of the prominent and most constant symptoms. The writer finds a satisfactory explanation of renal pain in such cases in tortion, or other temporary occlusion of the ureter, with consequent distention of the kidney. Courtin believes the pain due to pyelitis, and consequent nephritic colic. In one case, the writer found a displaced and movable kidney greatly enlarged from occlusion of the ureter by a calculus. So many patients have vague, indefinite, nervous, and dyspeptic sensations or symptoms, that it is not now thought possible to say any symptoms are pathognomonic. In the absence of a tumor it is impossible to say that such a condition exists. But those having given the subject careful attention, occasionally find explanation for various functional derangements of the vasomotor system, indigestion, gastralgia, or other epigastric or abdominal pain. All of my cases, including one in a male subject, had neurasthenic symptoms. One case may be mentioned to show how a patient can have peculiar, although in her case positive, symptoms enabling her to suspect the displacement of the kidney before its actual detection by the physician or herself. So closely related are the symptoms of displaced kidney to those of neurasthenia that a search for this abnormality is in every such case deemed important. Especially important is this in the absence of other explanation of neurasthenic symptoms. Given a neurasthenic, with emaciation, pelvic disease, such as ovarian or uterine inflammation, etc., we may expect to find many of these women with one or both kidneys movable. I am led to believe from experience in a recent case that epileptiform seizures may be exaggerated when the patient has a movable kidney. In one case, at least, the marked improvement following a nephrorrhaphy would justify the above statement.

Diagnosis.—A misplaced kidney is usually easy of detection, and its presence in a new position can be demonstrated. It is important to exclude distended gall-bladder or tumors of the liver, if the right kidney is in question. The spleen could not easily be mistaken for a kidney, unless enlarged or floating. Percussion is of but little value in locating a kidney anywhere, even in its normal position. Intestinal, omental, or pyloric tumors must all be considered, but, in each of these, concomitant symptoms will aid in the diagnosis. The characteristic and important test is the "slip," which all clinicians agree is pathognomonic. It is an available and pretty reliable test. It is obtained by bimanual palpation, one hand in the loin, the other on the abdomen. The pressure, beginning just under the rib, is continued downward. If the kidney is found, it may be felt to slide into place. When once felt it will always be remembered. The clinical history will often assist in the diagnosis, but we will often find an absence of definite symptoms here, while in organic diseases of the liver, spleen, or kidneys, we have what may be called definite, or positive, or objective symptoms. The writer has had difficulty in deciding between tumors of the gall-bladder, and misplaced and subsequently abnormally fixed kidney. Two cases present themselves to memory in which fixation occurred after the displacement downward of the right kidney. In one of these cases, now under observation, there is reason to suspect perinephritic inflammation, and tuberculosis is feared. A case will be reported hereafter in which the displaced kidney was greatly enlarged, its lower border reaching the iliac crest, due to temporary closure of the ureter. Finally in this, as in other diseases, mistakes have been made by competent observers. For instance, Mr. Tait once operated for gall-stone and found nothing abnormal. Dr. Baker of Auburn, N. Y., afterward cured the patient by a nephrorrhaphy. Mr. Tait declared the kidney was in its normal position.

Treatment.—Cases of movable kidney occurring in fairly healthy women (the displacement found by accident), may well go without surgical treatment, or be treated by a suitable bandage. I have but little personal experience with use of the

[1] Enteroptosis is in some cases responsible for descent of the kidney or kidneys with the intestines.

bandage in nephroptosis. The bandage is worn for a time, and then laid aside, or if it fails of its purpose, the patient may return for other treatment. It may be impossible, in fact it generally is impossible, to support a kidney by means of a bandage when it descends far below its normal position. However this may be, the writer would suggest a possibility of as much harm by pressure upon the intestine, as good or comfort from the bandage and necessary pad. On the other hand, if the patient is compelled to seek medical advice, having symptoms not otherwise clearly and satisfactorily explained, if she is emaciated and has one or both kidneys descending far below their usual position, it is possible that surgery may, and often does give as pronounced relief, and as much satisfaction to both patient and surgeon, as any other operation upon the abdominal organs (large tumors excepted). The writer desires to be clearly understood. We do not wish the operation to become as universal as trachelorrhaphy, or even as oöphorectomy, which required a vast, accumulated experience to stay the hands of men who did these operations upon the slightest pretext. Nephrorrhaphy—or nephropexy—in good hands, I believe to be a safe operation. It is, at least, comparatively so. While the very safety and convenience of this operation may make it possible that it be abused, we must not hesitate to make use of it in appropriate cases.

The writer has observed a large number of these cases during the past few years. Every observer who makes as careful examination of the abdominal as he does of the pelvic organs, will frequently find movable kidneys. That such careful examination is not *the rule*, we have every reason to believe. That clinicians invariably make careful search for disease or displacement of every organ is doubtful. That they often fail to detect a common misplacement of the uterus or kidney is absolutely certain. The condition under discussion is a case in point, for only a few years past can we say we knew much, or thought much, about "movable kidney." The failure to discover the condition lies in the hurried examination of patients, especially those in the dispensary. A patient must be undressed. She must have a flaccid abdomen and perfect quiet of mind and body if we would discover a movable kidney. The patient should be turned upon her side, or placed in the Trendelenburg, or the reverse position in some instances. Perhaps after repeated careful search by the physician, the patient may find the organ herself. In a case recently operated upon, the writer had trouble in finding the kidney when the patient was ready for operation. It had gone far up under the liver, and the patient had to be raised to the sitting position before it would come out of its hiding place. In this case the kidney moved from the diaphragm to the brim of the pelvis. Most important information is gained by operations which expose the kidney to view or the touch. In two of my cases, large distended kidneys became prolapsed and adherent. As already mentioned, one of these cases had a stone blocking the ureter. The enormous kidney filled the space between the rib and crest of the ilium. When the stone would shift from its position, a free discharge of urine would reduce the size greatly and give prompt relief. The kidney would then return nearly to its normal position. This patient waived operation until quite recently; she was subjected to nephrolithotomy in another city with fatal result. I have at present under observation a lady who had two large prolapsed kidneys. The left kidney was as large as a child's head, and far below its normal site. The enlargement was undoubtedly due to tortion or bending of the ureter. Nephrorrhaphy has cured this kidney. It was taken out of the fatty capsule, brought out of the wound, and carefully examined by sight and touch. Its vessels and pelvis, with a portion of the ureter, were palpated; then it was sutured to the wound, with entire relief of all symptoms, so far as that kidney is concerned. The right kidney will at an early day be likewise subjected to operation. In the half dozen or more cases operated upon by the writer, he has selected those cases actually in need of relief of symptoms. The patients were rewarded in every instance by the most pronounced relief. Never have more striking benefits been experienced from any operation than from nephrorrhaphy. The glow of health appears to return before the patient leaves her bed. In one case the patient gained nearly forty pounds in weight. Another patient was promptly relieved of vomiting and gastric distress, and gains in health and appearance. One patient, with two movable kidneys, sent me by Dr. Tompkins of Fredericksburg, Va., had one of them anchored with so much benefit that she writes to have the other kidney fixed. The only case thus far in which I have failed to have a perfect result, was sent be by Dr. Moran. She recovered nicely from the operation, gained immensely in weight, but had a recurrence, at least so reported. I am convinced that a perfected technic will secure better results hereafter.

Finally, and in conclusion, we recommend exploration, palpation, and inspection of certain

kidneys which have descended in the abdomen, because of added weight from distension, and when there is pus in the urine with a diagnosis of pyelitis.

Case I.—Mrs. H., referred by Dr. Tompkins of Virginia.

Both kidneys movable, the right less than the left. Patient has pain in region of kidney; nausea, neurasthenia, neuralgia; she has chronic salpingitis, adhesions, etc. Operation May 27, 1895. The loin was opened, the kidney brought into the wound and secured by one large silk suture, including muscle, fascia, fibrous capsule, and about ⅜ inch of substance of the kidney. The fibrous capsule was opened up ½ inch wide and 2½ inches long on the peripheral margin of the kidney. The edges of the capsule were sewed to the muscular walls of the wound, the usual gauze packing applied, the wound closed by silkworm-gut sutures. Although the patient vomited almost unceasingly for five days, the kidney was firmly fixed when she recovered, and has given her no trouble since. Dr. Tompkins writes April 27th, that "she is doing remarkably well since you fixed her movable kidney. She has gained twenty-five pounds in weight and looks ten years younger."

Case II.—Mrs. L., referred by Dr. J. E. Moran.

Had left nephroptosis. Right kidney anchored by another surgeon. I had previously operated upon this kidney through the abdomen. She has nervous and gastric symptoms. Operation June 27, 1895, at Columbia Hospital. The kidney fixed in the loin in a similar manner to that practised in the previous operation. Result, rapid convalescence and relief of symptoms. She gained about forty pounds in weight.

Case III.—Mrs. A., referred by Dr. Richardson, Hyattsville, Md. Operation at Columbia Hospital.

Double nephroptosis. Kidneys fixed, painful, and greatly enlarged; the center of the tumors on a line midway between umbilicus and spine of ilium. This patient had hematuria, and operation was done on left kidney as a tentative measure of relief. Operation December, 1895. The kidney was found very adherent to its capsule. It was brought out of the wound and found to be of normal size. It was evident that the enlargement was due to tortion or bending of the ureter. She has had a perfect result; no further pain, no hematuria, no symptoms of disease on that side. Drs. Busey and Bowen of this city, have since carefully examined this lady. They unhesitatingly pronounce the operation a success, and advise similar treatment of the right kidney. The patient is willing for the second operation when it is my pleasure to perform it. Three deep silk sutures were used in this case to secure the kidney to the wound.

Case IV.—Mrs. M., referred by Dr. Simpson, Manassas, Va.

Right nephroptosis. Gastric symptoms, neurasthenia. Tumor felt by patient, which greatly worried her. Kidney to pelvic brim, very movable. Operation at Columbia Hospital, March 4, 1896. Three deep silk sutures. Capsule sutured as before. Perfect result.

Case V.—Mrs. L., referred by Dr. Sohon.

Right nephroptosis. Symptoms referable to stomach and nervous systems. Patient has petit mal. Operation January 20, 1896, at the residence of patient. Recovery uneventful and symptoms relieved. Two deep transverse, and two loop longitudinal sutures, the latter so placed as not to close the wound over the denuded surface. Iodiform gauze is placed between the wound surfaces down to the denuded surface of the kidney for four to six days, when it is withdrawn and the wound allowed to close.

Case VI.—Mrs. G., referred by Dr. Walsh.

Has right nephroptosis; neurasthenia, nausea, vomiting, gastric distress. Operation advised by Drs. Walsh and S. C. Busey. Operation at private hospital April 23, 1896. Recovering from operation. Technic of operation same as one previous.

The six cases here reported comprise all operations with one exception. Case II had been operated in Chicago for right nephroptosis. I opened the abdomen to make a positive diagnosis and anchor the kidney. It was my first operation. The result was a return of the prolapse which the patient promptly recognized. She consented to the operation through the loin as noted above. She is reported to have experienced symptoms indicating a return, but it is not confirmed as yet. Of the three cases where the left kidney was movable, the right had been or was still movable. Of the operations on the right kidney, the patients had very slight or no displacement of the left organ.

FRACTURES OF BONES ENTERING INTO THE FORMATION OF THE ELBOW-JOINT.[1]

By BENJAMIN BRABSON CATES, M.D.,
of Knoxville, Tenn.;
Professor of Anatomy and Clinical Surgery in the Tennessee Medical College at Knoxville, Tenn.

Fractures of the bones entering into the formation of the elbow-joint may be confined to anyone of the bones that go to form this articulation, or it may involve all of them simultaneously. Thus, it may be limited to the lower extremity of the humerus, involving the external or internal epicondyle. Though Agnew says there are no well authenticated cases of fracture of the external epicondyle, Grainger, in 1818,

[1] Read before the Tennessee State Medical Society at Chattanooga, Tenn., April 14, 1896.

described a case of fracture in this locality. Should a single fracture occur on either side of the lower extremity of the humerus, extending from just above the condylar projection obliquely downward into the joint and displacing more or less of the articular surface of the bone with the condyle, there is presented what Holmes describes as a fracture of the outer or inner condyle of the humerus. According to Malgaigne, fracture of the outer condyle is the more common. He is substantiated by Hamilton and Agnew. On the other hand, Desault, who first described it, says fracture of the inner condyle of the humerus is the more common. He is corroborated by Sir Charles Bell, Sir Astley Cooper, South, and Holmes. Again, there may be a fracture through the base of the condyle known as supra-condyloid, or it may be limited to a splitting of the condyles, forming an inter-condyloid fracture; sometimes supra-condyloid is complicated with a fracture between the condyles, constituting what Ashhurst calls a T fracture.

On the other hand, the injury may be limited to one or both bones of the forearm. If the upper extremity of the radius is the seat of injury, the fracture may be limited to the head of the bone, chipping off a portion of its circumference or splitting it through the middle. Injuries of the head of the radius are likely to be associated with injuries to some of the other bones forming the elbow-joint. Holmes says, should it occur before puberty it is more apt to be a separation of the epiphysis. Again, fracture of the upper extremity of the radius is sometimes limited to the neck of the bone. That this fracture is rare, should be inferred by the differences of opinion among celebrated authors. Malgaigne thinks it uncommon; Mr. South says it is common; Sir Astley Cooper denied the existence of such a fracture; Hamilton is not convinced that it occurs, and Agnew says, "There are not more than one or two cases of such a fracture—verified by *post-mortem* examination—in existence." One of them is in the Mütter collection, belonging to the College of Physicians of Philadelphia. The writer has met with one case of fracture of the neck of the radius occurring in a woman, and reported in a paper read before the East Tennessee Medical Society at Knoxville, Tenn., May 24, 1894, which paper subsequently appeared in the *University Medical Magazine* for January, 1895. Agnew's table[1] shows "that of 648 cases of fracture of the radius treated at the Pennsylvania Hospital in Philadelphia, 24 were in the upper third, 53 in the middle third, and 571 in the lower third. In 542 instances the side was mentioned; 278 were on the right side, and 264 were on the left side. And in 777 recorded cases of the same injury, 477 were in males and 300 in females. Of this number, 733 were single; 21 compound; 10 compound comminuted; 6 single comminuted, and 7 not determined.

Fracture of the coronoid process of the ulna is, according to the "American Text-book of Surgery," almost unknown, except as a complication of dislocation of the elbow backward. This coincides with the observation of Holmes, who further states that it may occur without this complication. Holmes met with but three or four specimens, and recorded *post-mortem* examinations: one in the museum of Guy's Hospital, another in a man killed by a fall at St. George's Hospital, in whom both coronoid processes were fractured, and the two bones of the forearm dislocated backward on both sides, and the heads of the radii were split longitudinally. Hamilton collected twelve cases of fracture of the coronoid process. Of these, Sir Astley Cooper found one in the dissecting-room of St. Thomas' Hospital. Sam Cooper described one in the University College Museum. Velpeau reported one. The late Chas. Bell Gibson one. Lotzbeck of Munich, reported five, and Leo, three. Agnew is very doubtful if this injury ever occurs, having never met with it in his half century of practice. His tables show that of 133 fractures of the ulna admitted into the Pennsylvania Hospital, only three or four are noted as fractures of the coronoid process.

The writer has met with one case of fracture of the ulna, in the private dissecting-room of the Tennessee Medical College, without dislocation of any of the bones of the elbow or rupture of its ligaments. It was, however, complicated with a partial fracture of the external condyle of the humerus and splitting of the outer third of the circumference of the head of the radius, which can be seen in the accompanying plate. The subject, in which this accident occurred, had a fall from a bridge and sustained other injuries from which he died. In addition to the fracture of the bones of the elbow, he had fractures of the scaphoid, semilunar, os magnum of the carpus of the right hand, and also of the right ischium.

The causes leading to fractures of the bones entering into the formation of the elbow-joint may be direct or indirect violence, or to muscular action, as when applied to either epicondyle or olecranon process. When more than one bone

[1] Agnew, vol. i, p. 897.

is fractured, the cause is due to crushing forces applied from without, or perhaps furnished by the body of the individual—as falling from some high point and striking a hard object with the elbow, the weight of the body crushing the bones beneath.

The diagnosis of fracture of any of the bones at the elbow, theoretically, is comparatively simple, yet practically offers certain difficulties, due in a measure to the anatomical structures surrounding it, and again, to the distance from

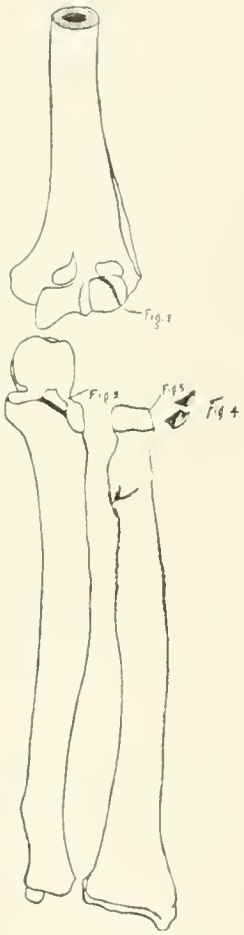

Illustration showing fractures of the bones of the left elbow-joint as found in a cadaver at the Tennessee Medical College. There was no luxation of the bones, or rupture of any of the ligaments. Fig. 1: Shows line of fracture through the radial head of humerus. Fig. 2: Fracture of coronoid process of ulna. Fig. 3: Fracture of outer third of circumference of head of radius. Fig. 4: Fragments of head of radius.

the surface of some parts of the bones entering into the formation of this joint—as in the coronoid process of the ulna and in the case of the radius —its neck. The diagnosis of injuries in this situation when of the condyles of the humerus, and not complicated by luxation of the bones of the forearm, if seen before there is much swelling, can be differentiated by grasping the condyles between the fingers and rubbing them to and fro. The condyles may be somewhat wider on the injured side than on the sound side. Should the fracture extend through the base of the condyles, there is in addition to the crepitus and preternatural mobility, shortening. When the olecranon process is fractured, there is gaping between the fractured process and shaft of the bone. There is not always the complete loss of power of extending the forearm as the books describe. Should the coronoid process of the ulna sustain a fracture, authors do not give any positive opinion as to the diagnosis, except at necropsy, though it might be felt in thin subjects and on firm pressure as a loose body in front of the joint. On the other hand, if the upper extremity of the radius is fractured, the close proximity of its head to the surface, offers the surgeon a better opportunity for manipulation; since by pressing upon the head of the radius with the thumb of one hand and grasping the hand of the patient with his other, he can, by pronation and supination, tell with a fair degree of certainty, provided the other symptoms of fracture be present, whether the head or the neck of the bone is the seat of injury.

The treatment of the fractures of the different bones entering into the formation of the elbow-joint will have to be met according to the exigencies of the individual case. If simple, and seen before there is much tumefaction, and involving the lower extremity of the humerus, the application of the roller bandage and an internal rectangular splint may be applied; or an anterior angular splint, well padded with a cap for the posterior surface of the elbow, is good. If the olecranon is fractured, the object is to keep the fragment in contact with the shaft of the ulna, which can be done by means of compresses with adhesive strips, fortified by figure-of-eight turns of the roller bandage, and by keeping the arm extended by means of a straight splint applied to the anterior surface of the arm and forearm. In case of simple fracture of the upper extremity of the radius, it is not always possible to treat the injury with internal angular splint, as recommended by Ashhurst. Then the surgeon is justified in using the plaster-of-Paris, keeping the forearm midway between pronation and supination. When there is a single fracture of the coronoid process of ulna, the application of a compress and binding the forearm to an anterior rectangular splint, is spoken of by authors. Should the trauma be of such a nature as to permanently injure the structures of the joint, as often happens in com-

pound fractures forming a liability to anchylosis, the arm should be placed in a position the most useful, which is nearly a right angle. In order to overcome the tendency to anchylosis, which so often obtains in fractures to any of the bones at the elbow-joint, it is well that the surgeon commence passive motion before the adhesions have undergone organization. Some surgeons recommend it as early as twelve days, while others say to wait two or three weeks.

A RESUME OF TEN MONTHS' OF VAGINAL WORK.[1]

BY EDWIN B. CRAGIN, M.D.,
OF NEW YORK.

THE principle that beaten paths are easier to follow than untried ways applies as well in surgery as in other walks of life. The abdominal route had become the one so often taken in attacking disease of the pelvic organs that the mere suggestion of using the vaginal route for this purpose seemed not only unnatural, but unwise.

Why leave methods which, in the hands of all of us, had not only proven themselves valuable, but seemed well-nigh perfect, for new methods, which all admit are as yet more difficult for the operator, and the technic of which still needs to be perfected? Would we not meet with hemorrhage, which we would be unable to control with any certainty? Would we not encounter other almost unsurmountable difficulties? These and many other misgivings haunted me when, on March 2, 1895, encouraged by the reports of other vaginal operators, I decided to convince myself of the value or defects of the vaginal route for removing diseased conditions of the pelvic organs.

Four features of the vaginal work impressed themselves upon me as having, in theory at least, advantages over the abdominal, and induced me to try the method:

1. Pus from ruptured pus-tubes and ovarian abscesses would flow downhill and away from the intestines, thus lessening the chances of sepsis.

2. The abdominal incision, with its tendency to hernia and unsightly scar, would be avoided.

3. Handling of the intestines would be lessened, and consequently intestinal adhesions would be few.

4. As another result of lessened handling of the intestines, shock would be diminished.

The object of this paper is to review carefully the writer's vaginal work of the past ten months, and ascertain whether the above anticipated advantages have been borne out in practice.

Whenever it has been possible to leave in the pelvis a comparatively healthy tube and ovary, or an ovary and a healthy portion of a tube, or even a health portion of an ovary, this procedure has been adopted, so that in a large proportion of the cases the uterus and one appendage, wholly or in part, have been left. During this period, from March 1, 1895, to January 1, 1896, my vaginal and abdominal sections have been equal in number, viz., fifty-five vaginal and fifty-five abdominal. In the fifty-five vaginal sections, both appendages were removed in only thirteen cases; and in three of these cases, in spite of the fact that both appendages were diseased and were removed, the uterus appeared to be so healthy that, after curettage and drainage, it was left in the pelvis. In cases where both appendages were removed, and the uterus showed marked endometritis, or the salpingitis involved the interstitial portion of the tube, the uterus was removed also. This was done in ten of the fifty-five cases. In reviewing his work, the conscientious surgeon is lead to ask himself whether he would do the same, were he to operate on the case again; in other words, has he any regrets? Of these fifty-five cases, which include all the vaginal sections, for all indications, done by the writer during the ten months above-mentioned, four have died.

One, Case XIV of the series was for *carcinoma uteri*, in which the disease had extended beyond the uterus—a case in which the radical operation should not have been attempted.

The second, Case XII, was one of puerperal septicemia, in which the uterus was removed, in the vain hope of getting beyond the septic process.

The third, Case XXII, was that of a large pelvic abscess in a patient very weak and septic, in whom one pocket of pus was opened and drained through the vagina, July 19th. Temperature and pulse came down, and patient improved, but on July 23d temperature and pulse rose again, and on July 26th patient was etherized, with a view of finding and opening, through the vagina, another pus-cavity. During the bimanual examination, and before any instruments were used, a large collection of pus escaped into the rectum. The patient was at once put to bed in fair condition, but died the next morning.

The fourth death can be justly assigned to the vaginal section, and seems to me the only one of the four which comes in competition with the abdominal operation. This was Case VII, in my list of vaginal sections. Mrs. L., suffering with double pyosalpinx, was operated on by me April 23, 1895. Both pus-tubes were removed, also the right ovary. The left ovary seemed healthy, and

[1] Candidate's paper presented for admission to the Am. Gynec. Soc., May, 1896.

was not removed; neither was the uterus. The patient died of sepsis, April 29th.

I have thought much over this case, and have wondered if the result would have been the same had the operation been performed from above. The pus-sacs ruptured in removal, and some pus escaped. The same thing would undoubtedly have occurred in the suprapubic operation. The pelvis was drained, and undoubtedly much better drained than it would have been from above. The case died, but, in the judgment of the writer, the same operation, if performed from above, would have brought the same result. Had the uterus been removed *per vaginam* at the same time with the tubes, the result would probably have been different.

Something should be said regarding the complications of vaginal section. Rectal fistulæ are rather more common after the vaginal operation than after the abdominal. One reason for this is, perhaps, the fact that our touch has not been as well educated in the feel of the pelvic organs from below as from above.

The technic of opening the peritoneum, without injuring the intestine, has not been as long practised or as well perfected below as above. Experience and practice will improve this. The spontaneous results, however, of fecal fistulæ occurring in the vaginal operation are much superior to those in the abdominal.

It has been my misfortune to have had five fecal fistulas. In three, however, there was a previous communication of an abscess with the rectum. The only one which did not close spontaneously was in Case XL, who had an abscess previously communicating with the rectum, and in whom the operation was begun *per vaginam* and finished from above; the uterus not being removed. This fistula had to be closed by operation three months later.

In the other four cases, the fistulas closed spontaneously; the first in sixteen days; the second in seven; the third in fifteen; the fourth in twenty-four, an average of fifteen and a half days. Rectal fistulas seem to close more readily when the uterus is removed than when it is left; also in those cases where the opening in the rectum is farther from the vagina, so that a longer granulating and contracting canal results, close, in the experience of the writer, more readily than those nearer the vagina.

One of the early objections raised to the vaginal method, is that the vagina does not furnish sufficient room for the work. Of course, additional room may easily be obtained by incising the perineum on either side, but that one soon becomes accustomed to the space furnished by the retracted vagina, is shown by the fact, that in only three of the fifty-five cases, was it found necessary to enlarge the space by incision.

The popular method at the present time for controlling hemorrhage and the pedicles, seems to be by the use of clamps, left on about forty-eight hours. Save in exceptional cases this does not appeal to me as the best method. Certainly, the patient is more comfortable when ligatures are used instead of clamps, and the sloughing is less. My own rule is to make use of clamps temporarily if at any stage in the operation they seem more convenient, but to use ligatures chiefly, and with certain rare exceptions, where the uterus is large and fixed, and the broad ligaments are markedly infiltrated, replace the clamps by ligatures before removing the patient from the table. If clamps are necessary, use as few as possible. In only four of the fifty-five cases have I left on clamps. Catgut has been my only ligature material. The cases which seem to me best fitted for the use of clamps are the puerperal cases.

The only vesical fistula which has occurred in the above series was in Case XXV, where, in an extensive epithelioma of the cervix, involving in one place the vesico-vaginal septum, a portion of the bladder was intentionally removed in order to get beyond the disease. This fistula was closed by operation some months later.

Of these 110 cases operated on by me during the last ten months of 1895, nearly all the pus cases were done *per vaginam*; in fact only four were operated on through the abdomen.

Comparison of the fifty-five vaginal with the fifty-five abdominal operations, done during the same time, although, at first thought, furnishing a rational criterion of the two operations, on further consideration does not seem the wisest plan, as the cases were so dissimilar, the vaginal operations being mostly suppurative cases, the abdominal mostly non-suppurative. The plan selected for comparison has been to table twelve cases of inflammatory disease of the appendages, selected in order of date of operation *per vaginam*, and compare them with twelve cases as nearly like them as possible, operated on through the abdomen during the year previous. These cases were taken in the order of date of operation, and the only guiding principle in their selection was to have them as similar to the vaginal cases as possible. They were diseased appendages with adhesions, chiefly pus-tubes.

It has been argued by the opponents of vaginal work that it requires a much longer time than the abdominal operation. These twenty-four cases taken for comparison were operated upon at the Roosevelt Hospital, where the time of each operation is noted. The average time in the twelve abdominal cases was 46 minutes and 5 seconds. The average time in the twelve vaginal cases was 40 minutes and 25 seconds; a gain over the abdominal route of 5 minutes and 40 seconds.

Let us now consider the four supposed advantages of the vaginal route, which were presented at the beginning of this paper, and see if experience has shown them real or fancied.

1. *Sepsis.*—Pus-sacs which have ruptured in removal have certainly discharged their leakage downward, and with less soiling of the intestines than would have been possible in the abdominal operation. Moreover, as we shall soon show from the temperature, pulse, and progress of the case after operation, there has been less sepsis.

In the twelve vaginal cases and twelve similar abdominal cases, which were taken for comparison, there were noted the highest pulse after operation, the number of days the pulse remained above 100°, the highest temperature after operation, and the number of days the temperature remained above 100°. The averages were taken and are as follows:

Vaginal cases: Highest pulse, 108½; pulse above 100, 1½ days; highest temperature, 100.8°; temperature above 100°, 2⅔ days.

Abdominal cases: Highest pulse, 114$\frac{5}{12}$; pulse above 100, 2⅙ days; highest temperature, 101.4°; temperature above 100°, 3$\frac{5}{6}$ days.

Difference in favor of vaginal route: In highest pulse, 5$\frac{1}{12}$; in pulse above 100, ⅔ day; in highest temperature, .6°; in temperature above 100°, 1⅙ day.

2. *Hernia.*— During the month of January, 1896, a large proportion of the fifty-five vaginal cases have been examined, and in none of them did I find a hernia, although they were examined with that in view.

3. *Intestinal adhesions.* — The two symptoms which would seem to indicate intestinal adhesions are abdominal pain and difficulty in moving the bowels. In my experience both of these have been less in the vaginal than in the abdominal operation.

4. *Shock.*—Perhaps the best way to reach a conclusion regarding the relative shock in the two methods of operation, is to compare the highest pulse-rate in the first twenty-four hours in the two series of twelve similar cases.

In the vaginal cases, the average highest pulse in the first twenty-four hours was 102¾; in the abdominal cases, 110. A difference of 7¼ in favor of the vaginal route.

Let me say, in conclusion, that in my vaginal work, I have found hemorrhage under control, and obstacles easily surmountable.

SPONGE GRAFTING IN THE ORBIT FOR SUPPORT OF ARTIFICIAL EYE.[1]

BY E. OLIVER BELT, M.D.,
OF WASHINGTON, D. C.

To a skilled oculist, the ordinary enucleation of an eyeball is one of the simplest operations he is called upon to perform, and yet there are some cases in which so much of the conjunctiva is destroyed by careless or ignorant operators, that it is impossible for an artificial eye to be worn afterward. This is very annoying to a patient, and we cannot blame him if he never forgives the doctor who has so afflicted him. Such cases emphasize the fact that it is the duty of the surgeon not only to operate skilfully for the immediate relief desired, but he should do everything in his power to prevent disfigurement, and when an organ or limb cannot be restored to usefulness, he should at least obtain the best cosmetic results possible. After an eyeball has been removed, and an artificial eye inserted, very frequently it is not as prominent as the good eye. It has a *sunken appearance*, which attracts attention at once to the fact that the eye is artificial. To remedy this defect has been a problem for ophthalmologists for years.

One of the most satisfactory operations heretofore practised is that known as Mule's operation, which consists in the evisceration of the contents of the eye, and the insertion of a hollow glass globe in the sclerotic, which is sewed in. This proved fairly satisfactory, but there is some danger of the globe being broken, and occasionally the stitches come out and the globe escapes. There is also the risk of sympathetic ophthalmia where the entire eyeball is not removed. To obviate these difficulties and at the same time secure a full orbit, I have devised a method of sponge grafting which seems to meet the requirements without the disadvantages of other methods.

The operation is a simple one, and is performed as follows: The eyeball is removed by the ordinary method under strict asepsis. After all hemorrhage is arrested, the socket is washed out with

[1] Read before the Medical Society of the District of Columbia, June 3, 1896.

formalin solution, 1–1000, followed by sterilized salt solution. A globe of fine, soft, sponge about three-fourths the size of the eyeball (previously sterilized in five per cent. formalin solution and rinsed in the salt solution), is then inserted into the socket, or capsule of tenon. The conjunctiva is brought together and sewed with rat-tail sutures. The eyelids are then closed with compress and bandage. In a few weeks the sponge is filled with new tissue, which in time becomes firm, solid flesh, making a full orbit and a fine support for the artificial eye. The sponge fibers are apparently absorbed.

I have performed this operation in five cases with fairly good results in all, but union of the conjunctiva has not been firm enough to prevent some of the stitches from breaking or cutting out and the wound gaping. In future cases, to relieve this strain on the conjunctiva and to obtain good motion of the eye, I think of uniting the opposing recti muscles with rat-tail sutures, and then the conjunctiva over that by the purse-string or subcutaneous suture. By this method we should get union by first intention, good motion of the stump, and a full orbit. There seems to be no danger from infection of the sponge, for in two cases the eye was removed for panophthalmitis. Not only has this operation advantages over other methods in recent cases, but in old cases in which the eye was removed months or years ago, when there is this sunken appearance of the artificial eye, the socket might be reopened and a sponge inserted.

Since making my investigations, I find that Professor D. J. Hamilton of Edinburgh, practised sponge grafting for old ulcers in 1880, since which time a few other physicians have tried it in fresh wounds, and some other similar conditions that skin-grafting had been used in. However, I cannot find in all the medical literature in the library of the surgeon-general's office any mention of sponge being used as I have suggested and tried.

SURGEON LIEUTENANT-COLONEL LAWRIE thus describes in the *Lancet* the use of mercuric chlorid in treatment of hydrocele: "The sac is punctured in the usual way, and when about one-third or one-half of the fluid has been withdrawn, two drams of a saturated solution of bichlorid of mercury in glycerin are injected and mixed with that which remains, and allowed to rest in the sac for from half a minute to a minute. The whole of the fluid is then drawn off to the last drop. Very little pain is experienced, and, unless the patient is nervous or takes chloroform, he is able to move about immediately after the operation."

CLINICAL MEMORANDA.

THE COMPARATIVE VALUES OF HOMATROPIN AND ATROPIN AS MYDRIATICS.

BY FLORENCE MAYO, M.D.,
OF PHILADELPHIA, PA.;
INSTRUCTOR IN DISEASES OF THE EYE IN THE PHILADELPHIA POLYCLINIC.

ALTHOUGH the action of homatropin hydrobromate upon the eye has been carefully studied since 1881,[1] its reliability as a mydriatic is doubted by many ophthalmologists. In order to test the relative values of homatropin and atropin, I refracted the following cases, at the suggestion of Drs. Jackson and de Schweinitz, in their clinics at the Philadelphia Polyclinic.

Homatropin was first used, and while the eyes were yet under the influence of this drug, atropin was instilled thus producing a continuous mydriasis and allowing the atropin to act upon a ciliary muscle which was already paralyzed as much as homatropin was capable of producing this condition.

The use of the homatropin was not trusted to the patient, but the instillations were made by myself at the clinic. The strength of the solution used was gr. 1 to 40 minims of water. Six drops of this were used at intervals of five minutes, one hour before the test was made. The condition of the refraction was then measured by skiascopy and subjectively at the test case; and the same procedures were employed to ascertain whether any accommodation was present. The cases were selected only to the extent of excluding those patients who were not sufficiently intelligent to respond to the subjective tests. The ages of the patients ranged from eleven to thirty-nine years.

As soon as the refraction under homatropin was completed, the patient was given a solution of sulphate of atropin, gr. ss. to fl. ʒ j, with directions to use one drop in each eye three times daily, and to return to the clinic after a two days' use of the drops. The second refraction was then done.

The homatropin and the atropin used were from Merck's laboratory.

Conclusions: The table shows that the atropin confirmed the measurement made under homatropin; that it failed to reveal any error of refraction which the homatropin had not already uncovered, and that if homatropin be properly used it is a reliable mydriatic.

REMARKS.—No. 2 refracted three months previously under duboisia with like result. No. 55 refracted under atropin three years previous to that under homatropin.

AN UNUSUAL VIBRATORY CICATRIX IN THE MEMBRANA TYMPANI.

By J. E. SHEPPARD, M.D.,
OF BROOKLYN;
PROFESSOR OF OTOLOGY, LONG ISLAND COLLEGE HOSPITAL, AND AT THE NEW YORK POLYCLINIC; AURAL SURGEON, BROOKLYN EYE AND EAR HOSPITAL.

EDWARD B., aged thirty-eight, driver, was first seen at the Brooklyn Eye and Ear Hospital March 31, 1896, and examined at length the next day. He says that in childhood he had recurrent attacks of pain and discharge in both ears, which he attributes to bathing and diving; that, since then, he has had in both ears tinnitus and deafness, worse in the right ear until the last two years, during which the deafness has grown worse in the left ear. At present H. D. w. R. 3/60, L. 1/2/60; wh. and conv. R. ca. 24′, L. 18′. Tuning forks; from vertex, louder in the left ear; in the left ear, B. C. louder than A. C. for forks c and c″, for c‴ A. C. louder than B. C. The absolute duration of air conduction exceeds that of bone conduction for all three forks. In the right ear, A. C. louder and longer than B. C. all the way through the Hartmann series. Upper tone limit, as shown by the Galton whistle, 5.3 for right ear, 5.5 for left ear.

Right m. t.; malleus in normal position; the smaller, anterior half of m. t. present, and the seat of a medium-sized chalk deposit, and of a full-sized, but broken, light reflex, the larger, posterior half consists of a depressed, at one point, adherent, cicatrix. Left m. t.; great retraction, marked opacity, except of a small anterior inferior cicatrix: light reflex diffuse and dim. Both Eustachian tubes open freely to Politzerization.

The intranasal conditions are such, from moderately enlarged turbinateds on right side, and crest running along left side of septum, that under quiet conditions he can just succeed in breathing through the nose, but in case of any exertion, and probably to a considerable extent when sleeping, his breathing is largely oral.

The unusual part of the case is the behavior of the posterior cicatrix in the right membrane: Whenever the man speaks or swallows, but not with the pulse or respiration, there is very perceptible vibration of the upper half of this cicatrix. This vibration occurs with every sound of the voice, with the letters of the alphabet, as well as with words, the one thing noticeable in this connection being, what appears to me, the fact that there is a smaller vibration for the letters m, n, o, and r, than for the rest of the alphabet. The first part of the vibration is inward, followed by the rebound outward, and so on, indicating, it

seems to me, that the immediate effect of the phonation is in this case the formation of a partial vacuum in the tympanic cavity.

Is this phenomenon due to the physiological effect of phonation upon the air contained in the tympanum, or is it pathological? If it is pathological, and this seems to me the more probable explanation, then it is due to the existing, slightly obstructive, nasal condition, on the same principle that mouth-breathing is considered to tend always to the exhaustion of the air in the tympanum.

Viewed in this light it perhaps explains the symptoms about which I have recently been consulted by a gentleman, who, several days in the week, is obliged to do considerable public speaking. By evening of the days when he speaks most, he has an uncomfortable, stuffy feeling in the ears, from which feeling he is quite free on those days when he does no public speaking. This patient has also a very slightly obstructive nasal condition, not sufficient to cause mouth-breathing except after very considerable exertion. In both cases the treatment will consist of the re-establishment of free nasal respiration.

If any apology is necessary for bringing this case to the notice of the profession, I would offer a two-fold excuse, viz.: In the first place, while I, with probably many others, have seen cicatrices vibrate synchronously with the pulse, and with respiration, it was to me a novelty to see one affected by every sound of the voice; and in the second place, because it opens up a question, possibly physiological, but much more likely pathological, for our consideration, and may possibly be the means of explaining an occasional, otherwise obscure, case.

MEDICAL PROGRESS.

The Urology of Cataract.—As the result of an investigation covering a period of three years and involving 335 examinations in 259 cases of cataract of all kinds, except the traumatic variety, FRENKEL (*Lyon Médical*, 1896, No. 14, p. 466) found that the quantity of urine excreted in twenty-four hours by such patients under hospital regime in a state of either absolute or relative repose, presented a diminution greater than could be accounted for by the conditions of observation. The density of the urine approached in the mean that of persons with normal diuresis, thus indicating that the secretion of the urinary salts was diminished. It was further found that the elimination of urea was considerably diminished in most of the patients, and this diminution was due not only to the age of the patients, the alimentary regimen and the repose, but probably also in part to the diminution in the bodily metabolism. The elimination of the chlorids was found to be normal or exaggerated. The phosphates were diminished in some, normal in others, and increased in still others. Cases of cataract with phosphaturia were not very rare; they were less rare than cases with glycosuria, of which the proportion was 1.16 per cent. Neither the diabetes nor the cataract presented any special gravity, nor did special difficulty attend surgical intervention with antiseptic precautions. So-called physiologic albuminuria was found to be as common in cases of cataract as in any other group of individuals. Pathologic albuminuria was observed in a proportion of only 0.6 per cent. Peptonuria may be observed in cases of cataract, particularly in persons not kept in bed, but this condition bears no special relation to cataract.

A Fatal Case of Petroleum Poisoning in a Girl of Two Years.—JOHANNESSEN (*Berliner klinische Wochenschrift*, 1896, No. 15, p. 317) has reported the case of a girl, two years old, who, when seen several hours after swallowing an uncertain amount of ordinary coal oil, presented general pallor, with cyanosis of the lips, and difficulty of breathing. Consciousness was not lost, though blunted. The pupils were not dilated and reacted to light. The lips and tongue presented no peculiarity, while the tonsils appeared to be slightly swollen. The pulse was rapid and irregular, though the heart-sounds were distinct. Respiration was accelerated. The temperature was normal. Signs of rachitis were present. Introduction of the finger into the pharynx induced free vomiting; the vomitus contained, in addition to a little blood, a good deal of mucus, and smelled strongly of coal oil. The stomach was washed out through the tube and a half hour later vomiting was again induced. The pulse improved upon the subcutaneous injection of fifteen minims of camphorated oil, and the child appeared to improve. The bowels were evacuated by enema, the discharge emitting an odor of coal oil. Later, however, the child again became drowsy, the respiratory difficulty returned, the pulse became weaker and more irregular, and finally death ensued. Upon *post-mortem* examination, about an ounce of clear yellow fluid, smelling feebly of coal oil, was found in each pleural cavity; the serous membrane itself was smooth and free from ecchymoses. The lungs were somewhat edematous, the expressed fluid possessing a slight odor of coal oil. They were heavy and dark in color. The lower lobes and the adjacent parts of the upper lobes failed to crepitate, and portions sank in water. The glands at the root of the lung and surrounding the trachea, as well as some of the glands of the neck, were swollen but not cheesy. The cavities of the heart contained clotted blood, some of which extended into the large vessels. Peyer's patches and the solitary follicles were somewhat injected and swollen. The mesenteric glands were found to be enlarged and hyperplastic. The veins of the cerebral membranes were somewhat hyperemic. Otherwise no noteworthy changes could be detected.

The Treatment of Pneumonia with Guaiacol in Spray.—MALDARESCO (*Semaine Médicale*, 1896, No. 19, lxxiv) reports the results obtained in the treatment of more than one hundred cases of pneumonia by means of guaiacol employed as a spray upon the external surface. The use of the medicament is begun in antithermic doses as soon as the diagnosis is determined, the application being made to the posterior aspect of the thorax upon the affected side, and covered with a layer of absorbent cotton held in

place by a bandage. When the antipyretic effect has disappeared and the temperature has fallen to 38° C., (100.4° F.) the application is repeated at the end of three or four hours. This course is pursued until the temperature remains permanently at the normal. In mild cases, such a result is often obtained at the end of two days. When the apyrexia is established quinin is given in doses of four grains daily, in conjunction with alcohol. In the course of the treatment thus carried out, cough diminishes, expectoration becomes easy, and the sputum loses its viscosity and its rusty coloration. Favorable results were secured not only in cases of fibrinous pneumonia, but also in some of broncho-pneumonia. Care must be exercised in the treatment of the very young and the aged; in the former it is well to use a forty per cent. mixture of guaiacol with almond oil, and make the application successively upon the anterior, posterior, and lateral aspects of the chest.

The Application of Artificial Leukocytosis to the Treatment of Septic Puerperal Processes.—Hofbauer (*Centralblatt fur Gynäkologie*, 1896, No. 17, p. 441) details a series of observations in which nuclein was employed to induce artificial leukocytosis in the treatment of a number of puerperal women suffering with septic processes, The action of the therapeutic agent proved prompt, and free from unpleasant manifestations. The administration by the mouth was followed by the appearance of nucleinic acid in the chyme. The effects of the treatment manifested themselves by improvement in both the general and the local conditions.

The Employment of Anti-streptococcus Serum in the Treatment of Scarlatina.—Baginsky (*Berliner klinische Wochenschrift*, 1896, No. 16, p. 340) reports the results secured in forty-eight cases of scarlatina between October, 1895, and March, 1896, in the course of which the anti-streptococcus serum of Marmorek was employed. In twenty-seven the course of the disease was unusually favorable, the majority recovering without complication. Only four were attended with suppurative otitis; one with mild nephritis; in two others severe anginas developed; in one case acute and painful glandular enlargement followed the injection, but recovery ultimately ensued. A striking feature in all was the rapid reduction of the temperature. It was further remarkable that in only two cases did severe anginal symptoms appear in the course of treatment with the injections. Ten cases in which such symptoms were present on admission terminated in speedy recovery. In exceptional cases albuminuria appeared, and in a single case nephritis with tube-casts, blood-corpuscles, etc. In a second group of cases of severe type the results were not so happy, although it is possible that in these the amount of serum employed was insufficient. It appeared, however, as though the cases were refractory to the therapeusis. In a third group of cases, five in number, the serum was employed only for the relief of complications arising late in the progress of the disease. In four of these cases the results were satisfactory; in one, complicated by ulcerative endocarditis, death ensued. Among the whole number of cases there were seven deaths, 14.6 per cent., as compared with percentages fluctuating between 22.6 and 34.4 in the years from 1890 to 1895. The mortality among cases treated with other means during the same epidemic as that in which the serum was employed was 24.9 per cent. The secondary manifestations attending the injections were similar to those observed in the sequence of injections of diphtheria antitoxin.

The Function of the Suprarenal Bodies.—As the result of an experimental study Dubois (*Archives de Physiologie*, April, 1896, No. 2, p. 412) arrives at the conclusion that the principal function of the suprarenal bodies is the destruction of toxins present in the circulation, and especially of the waste products of muscular activity and perhaps also those resulting from nervous activity. The glands do not appear to secrete any particular substance destined to be thrown into the circulation for the purpose of destroying or modifying noxious products constantly produced as a result of cellular activity, or gaining entrance from without. The cellular protoplasm of the capsules appears to possess a peculiar diastasic property not of a toxic nature which seems to be capable of exercising a modifying influence upon certain organic poisons, bacterial or otherwise, an influence requiring for its manifestation a certain period of time, and which may be exerted gradually. In the normal state the medullary zone contains alkaloids of intensely toxic activity, whose effects appear to be exerted especially upon the striped and unstriped muscular fibers. These alkaloids represent excrementitious matters whose retention is followed by the development of constitutional manifestations. They vary widely under different conditions.

THERAPEUTIC NOTE.

The Treatment of Pruritus Vulvæ. — While admitting that pruritus vulvæ may be purely a nervous manifestation, Ruge (*Berliner klinische Wochenschrift*, 1896, No. 18, p. 391) states that with the exception of a small number of cases in which some constitutional disorder existed, the pruritus in his experience was the result of local irritation, of disease of the external genitalia of the vagina and the portio vaginalis. The irritant is assumed to be of chemic or bacterial nature. In accordance with these views, success in treatment will depend upon the application of antiseptic principles. Without removal of the hair of the mons veneris, the vulva, vagina, portio vaginalis, and the cervix within reach of the finger are carefully soaped, without the use of a brush, and the vulva and vagina washed with mercuric-chlorid solution until rendered thoroughly aseptic. Then the affected parts are rubbed with a vaselin ointment of the same, in strength from three to five per cent. These procedures must be repeated every three or four days. The results obtained with this plan of treatment have been entirely satisfactory. A similar course may be advantageously employed in the treatment of recent gonorrhea in the female.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

THE ANTITOXIN TREATMENT OF DIPHTHERIA.

No scientific question before the medical profession is of more vital interest at present than the determining of the real efficacy of antitoxin in the treatment of diphtheria. The serum treatment of disease is on trial, and on the verdict that shall now be given are centered the high hopes of scientific medicine. Resting on the well-grounded basis of the germ theory of disease there has been elaborated the most logical and theoretically perfect system of therapeusis. Its practical application under the searching eye of skilled observers in a few special hospitals of Europe demonstrated its usefulness to a sufficient degree to commend it to the profession for more extended trial.

Questions in therapeusis are notoriously complex and difficult of solution. So many varying factors enter into the problem such as the tendency of acute diseases to spontaneous recovery, the diversity in the resistance power of the individual, the uncertainity in diagnosis, the possibility of intercurrent infection, etc., that the most carefully formed decision is never absolutely impregnable. It behooves the investigator therefore to carefully weigh all factors of uncertainty and welcome all honest criticism as a help to final truth.

The most elaborate and searching discussion that the subject of antitoxin in diphtheria has received in this country was presented before the New York Academy of Medicine, occupying entire time of the two last meetings. This appeared in a most complete form in our last issue. The discussion was based upon observation and reports of the use of antitoxin in *hospital* practice. Next week we shall print in full the carefully revised, official report of the American Pediatric Association which comprises an analysis of several thousand cases reported from the *private* practice of over six hundred different physicians.

Such a broad field of observation under the conditions to which the practical use of any remedial agent must finally be subjected will render this report one of the most valuable pieces of evidence that can be submitted to any tribunal. On the conclusions thus deduced will doubtless rest the future, in this country at least, of the antitoxin treatment of diphtheria.

THE FORMALIN TREATMENT OF WOUNDS.

IF a watery solution of gelatin be allowed to dry in formalin vapor, the gelatin loses altogether its customary characteristics. It is no longer affected by hot or cold water, nor by steam, nor by acids, nor alkalies; and the formalin which has entered into combination with it is chemically inactive. Experiments upon animals, however, proves that by the action of the living tissues the combination is broken up and formalin set free. Further experiments upon pigeons and dogs revealed the fact that if formalin gelatin is ground to a fine powder, mixed with colonies of bacteria, (staphylococci, streptococci, chicken cholera) and introduced into the animal, the germs are unable to grow and the wounds heal without reaction.

This result is apparently due to the action of the freed formalin, an action which continues for some time—several hours probably—and therein lies an advantage of this new material over all the old antiseptic agents. Schleich (*Therapeut. Monatsch.*, February, 1896) asserts that with the help of this material every acute suppuration can

be stopped in twenty-four hours, and every wound can be made to heal aseptically without further trouble. He has proved this by its use in 120 cases of acute suppuration, 93 aseptic wounds, 4 compound fractures, and 2 deep wounds of the scalp. In his experiments the principles of aseptic surgery were in all respects observed, except as to the wounds, which were only mechanically cleansed and thoroughly rubbed with the powder. In every case suppuration was stopped in twenty-four hours, and even the compound fractures healed without any fever. In fresh wounds the powder made with the blood a firm aseptic scab.

In order to be of service the powder has to be brought into contact with sound or inflamed tissue. In the presence of necrotic masses, or in the specific inflammations of syphilis and tuberculosis, it has very little effect. In order to produce a continuous supply of formalin vapor for the treatment of ulcers, etc., it is possible to digest the formalin by a pepsin-hydrochloric acid solution. The formalin-gelatin powder is first dusted on the wound, and then covered with a compress wet in a watery solution containing five per cent. of pepsin and .3 per cent. of hydrochloric acid.

The powder is made by drying 500 grams of purified and dissolved gelatin in the vapor of 25 drops of formalin. The gelatin is then rubbed to a powder and preserved in the presence of a single drop of formalin solution.

THE COMMISSIONERS OF CHARITIES OF NEW YORK CITY, AND A SECRET CURE FOR DRUNKENNESS.

The action of the Commissioners of Charities in setting apart two wards in Bellevue Hospital for the trial of a secret so-called "cure for drunkenness" is most deplorable. Not only is it inimical to the best interests of Bellevue Hospital and an unwarrantable affront to the medical profession, but it is the embodiment of a mistaken idea on the part of the Commissioners of Charities as to what their duties to the people are.

The owner of this so-called cure, a physician of this city, has tried for a number of years past, and, we believe, without material encouragement, to secure the approbation of physicians for a secret method of treating inebriety. It needs no explanation to show why such approbation has been withheld. One of the first principles which an individual who aspires to become an honest physician has thoroughly ingrained upon his conscience is that it is beneath his dignity as a man and inconsistent with his honesty as a physician, to withhold for personal and selfish gain any discovery which might be the means not only of mitigating the sufferings of the afflicted but of advancing the position of the profession of which he is a member. If his conscience becomes so blunted that this truism does not appeal to him, it is an unwritten as well as a written principle of ethics that he, by reason of such contemptuous acts, ceases to be a member of the profession in good standing, and that the honest members of the profession should disdain to have any intercourse whatever with such a person, or to make any use of the methods which appear to him of such intrinsic worth that he cannot afford to share them with the general profession.

Naturally, the individual who could resort to such quackish methods, would be extremely desirous of making his self-styled "wonderful discoveries" as well known to the undiscerning public, as possible, and in this instance no better scheme of bringing it before the public could have been concocted; for from the very first day the daily press has been filled with reports, apparently inspired, of the wonderful results which are obtained by the drink cure of Dr. ——— which is now being tried at Bellevue Hospital. Even after so short a time as three days, the superintendent of that institution, in the fulness of his therapeutic wisdom and diagnostic perspicaciousness, said to the reporters "It is the most wonderful thing I ever saw" and then his enthusiasm running away with him and becoming dramatic, he is reported to have said "it is a God-send."

To his eye the training of which has been obtained until a few weeks ago in a calling quite foreign to that of the medical profession, for he was a plumber, "the change in them is remarkable." To quote his own pithy sentence, "They look better, their eyes are brighter, and their step is not so slow."

The Commissioners of Charities who have done this overt act in this instance, we are informed, at the request of his Honor, the Mayor, are evi-

dently laboring under a mistaken conception of what their duties to the citizens of this city are. They are appointed that the charitable aims of the city may be carried out to the best advantage, and that those deserving of charity, the infirm, the incapacitated, and the sick shall derive the greatest benefit from it. It is not a part of their duty to make experiments or trials to discover the efficacy of therapeutic measures, of drugs, or of instruments. If it seems necessary to determine the value, or lack of value, of any medical measure for the benefit of the sick the proper persons to make such estimation are the visiting physicians, and not some outside person who may pray for the privilege.

It behooves the Committee of Inspection of Bellevue Hospital to lay aside the attitude of supine indifference and bring this matter clearly to the attention of the Commissioners. After they have done this commendably and without cavil, they should say to the honorable Commissioners that no secret measures, no measures protected by law, heralded though they may have been by some modern Mercury, approved of pontifically, and advocated by royalty, aristocracy, and plutocracy, have ever been the means of advancing the position of medical science one particle nor of ameliorating sickness or righting moral shortcomings.

If such enlightenment arouses in them a proper sense of their duties, they will at once put a stop to an experimentation which can only revert to the benefit of one—the worthy owner of an unworthy measure.

RESUME OF RECENT PROGRESS IN NEUROLOGY.

AT the recent meeting of the American Neurological Association two subjects of general interest were discussed: that of cerebral surgery, especially in its relations to epilepsy, and cerebritis. Great as were the expectations aroused at one time by the development of cerebral and cerebellar localization and its application by the surgeon to the removal of intracranial neoplasms, those who have had most to do with the subject have been gradually more appreciative of the defects in our present neurological knowledge and surgical methods. The discussion in Philadelphia only served to emphasize these. It is a matter of regret that the time allotted for debate was insufficient to permit of a full discussion. The truth is that we can only locate the cortical centers for the upper and lower extremities, the motor elements of speech, hearing, smell, perhaps also agraphia, while the localization of the other sensations and the different portions of the cerebellum is still open to doubt, and the site of the other mental faculties remains extremely uncertain. It is true that we can localize with remarkable accuracy at the base of the brain, the basal ganglia and the pons, but these structures are beyond the profitable reach of the surgeon's knife. Our information, therefore, although large, is by no means complete. Moreover, we have no means, before the operation, of differentiating between lesions of the cortex and the sublying white matter, and even at the operation a subcortical neoplasm can only be detected by probing with a needle, very often unsuccessfully; indeed, in one case, a well-known neurologist of this city never found the tumor until sections had been made of the brain after months of hardening, while the writer ran a needle three times (as was afterward demonstrated) through a round-celled sarcoma with a central cystic degeneration just below the cortex, and yet the surgeons could not find the growth, which came to view during careful *post-mortem* dissection. Multiple neoplasms may be present, too, as in a case of the writer's, where a melanoma was removed from the cortex of the cuneus without relief of the hemianopsia, because, as was shown by the necropsy a month later, there were several melanotic tumors throughout the optic radiations. To these obstacles there must be added another in cases of epilepsy, and that is the important question, whether the convulsions can be abolished by a successful removal of the lesion causing them. Many years ago the writer called attention to the fact that cases of epilepsy were reported as cured because the convulsions had been lessened in frequency or violence for short periods after resort to various operations and medicaments, evidently from the lack of appreciation by the reporter that much more favorable variations were frequently obtained spontaneously. In the writer's article in "Dercum's Text-book of Nervous Diseases" many cases are analyzed from this point

of view, to which number Mason has subsequently added others, showing that out of seventy patients only three were really cured in the sense that the attacks had ceased for three years after operation, while six were improved, fourteen were not improved, three died, one relapsed, two improved, but with bromids. The consensus of opinion at Philadelphia was in accordance with this view, although one speaker would have us take a standard of two years as sufficient to prove a cure; but it is difficult to perceive why we should do so. One gentleman made a curious suggestion that none but surgeons who had grown experienced and expert in cerebral surgery should ever operate. The question would fairly arise: How are operators to gain experience if they wait until they have obtained it? Notwithstanding these difficulties of the neurologist and the surgeon, however, there can be no question but what there will be a much more effective surgery of the future made possible by the constant advance in localization and in operative technic; and in the modern photography so unexpectedly afforded us by the Röntgen ray, and even in the immediate future we shall be greatly aided in this onward march by the skiagraphs of brain-tumors, which several gentlemen are already claiming to make.

Of greater interest to the physician was the very instructive paper of Putnam, upon "Hemorrhagic Cerebritis," and the ensuing discussion, which demonstrated, as has been shown by recent literature abroad, that cerebritis is a much more frequent disease than is generally supposed, and that it is very often clinically indistinguishable from meningitis, even the classical sign of retraction of the head being common to both affections.

Landon Carter Gray, M.D.

ECHOES AND NEWS.

Dr. Herman Knapp, the well-known oculist of New York, narrowly escaped drowning at Monmouth Beach, N. J., last Saturday. He was only rescued by the prompt and heroic assistance of his daughter.

The first death in Ward 33 at Bellevue Hospital, which was set apart recently for the treatment of chronic alcoholic cases with a secret preparation, was reported early this week.

A meeting of the executive committee of the Mississippi Valley Medical Association was held at Atlanta, on May 6th, and the following gentlemen were appointed to deliver addresses: Dr. H. N. Moyer, Chicago, address on medicine; Dr. Horace H. Grant, Louisville, address on surgery. The indications are that the meeting to be held at St. Paul, on October 20th, 21st, 22d, and 23d, will be the largest and most successful in the history of the Association.

Dr. Henry P. Walcott of Boston, has been elected president of the Massachusetts Medical Society for the ensuing year.

The American Surgical Association, at its annual meeting at Detroit, elected Dr. J. Collins Warren of Boston, president.

Dr. G. Frank Lydston of Chicago, has a book in press entitled: "Over the Hookah; the Tales of a Talkative Doctor," that will present humerous and pathetic character sketches and studies.

The Bowman Lecture before the Ophthalmological Society of Great Britain, was recently delivered by Professor Snellen of Utrecht. His subject was "The Influence of Light on Vision."

The Paris Faculty of Medicine has caused Dr. Roger, chief of its pathological department, to resign because he had been indirectly engaged in the secret manufacture of anti-streptococcic serum. Dr. Marmorick of the Pasteur Institute, was the first to present the claims of this new remedy.

Advices received from Korosko, Egypt, announce that cholera has made its appearance among the Egyptian troops at that place. The dispatches say that fourteen cases of the disease were discovered in the camp, seven of which had resulted fatally up to the time of writing. The advices add that great fear is entertained that the disease will spread throughout the Soudan expedition.

Harvard University, on behalf of its Medical School, has filed a bill in the United States Court in Chicago against the Harvard Medical College of Chicago, seeking to enjoin the latter from the use of the name "Harvard," as being a fraud upon the University and the public.

M. Metchnikoff, M. Roux, and Salimbani, of the Pasteur Institute, have been so far successful in their endeavors to prepare a cholera antitoxin that, by its use, they can save many of the rabbits infected with cholera virus, while the control animals invariably die.

Dr. Howard A. Kelly, in the *Johns Hopkins Hospital Bulletin*, has expressed his complete confidence in sterilizing of catgut with cumol. His approval was, in effect, that we now have a perfect method of sterilizing catgut with cumol, boiling at 155° centigrade, and we can use the gut with perfect freedom without fear of after-trouble. We are, therefore, almost as well off as if we used torsion; we simply add a little absorbable animal substance which disappears in a few days when it has done its work.

THE following letter from Jefferson to Jenner is copied from the *Brooklyn Medical Journal* for June. It shows how prompt Jefferson was to accept the new treatment. He and other members of his family personally practised the operation among their own connection and adherents:

MONTICELLO, Va., May 14, 1806.

SIR: I have received the copy of the evidence at large respecting the discovery of the vaccine inoculation, which you have been pleased to send me, and for which I return you my thanks. Having been among the early converts in this part of the globe to its efficacy, I took an early part in recommending it to my countrymen. I avail myself of this occasion to render you my portion of the tribute of gratitude due to you from the whole human family. Medicine has never before produced any single improvement of such utility. Harvey's discovery of the circulation of the blood was a beautiful addition to our knowledge of the ancient economy; but on a review of the practice of medicine before and since that epoch, I do not see any great amelioration which has been derived from that discovery. You have erased from the calendar of human afflictions one of its greatest. Yours is the comfortable reflection that mankind can never forget that you have lived; future nations will know by history only that the loathsome smallpox has existed, and by you has been extirpated. Accept the most fervent wishes for your health and happiness, and assurances of the greatest respect and consideration.

TH. JEFFERSON.

THE Berlin letter to the *Press and Circular* states that several changes in the personnel of the Institute have recently been effected. It is now just twenty years since the Institute was opened with two members—one for the medical and one for the veterinary department. Since then the number of members has steadily increased. There are now eight ordinary members, besides a number of associates. Another member is provided for, however, in next year's estimates, as the present staff is quite inadequate for the work demanded. The new member will undertake the department of public health, so far as it concerns food adulteration and offensive businesses. Dr. Josef Brandl, until recently at Munich, has been called to the new position, under the title of Regierungsrath, or Member of Council. He has for several years been Professor Tappeiner's assistant at the Pharmacological Institute at Munich.

ACCORDING to the *Medical Press and Circular* the coming scientific conventions in Germany will have many improvements in the Röntgen discovery laid before them. The latest news is that the apparatus has been so modified that a picture of the internal structures of the body can be thrown upon the fluorescent screen. The General Electrical Association announce from Berlin that it is possible, in this way, to demonstrate the internal structure of the head, larynx, and more especially the action of the respiratory organs and heart. If this be the case, it will simplify diagnosis of many organic lesions to a marvelous extent. Indeed, recent improvements in the new photography give promise of a future in scientific medicine that may be described as marvelous and revolutionary. Not the least remarkable feature of the matter is the lightning-like rapidity with which the whole subject of the X-rays has been investigated all over the world since the announcement of the discovery in the early part of the present year. It is announced that a practical demonstration of the fluorescent internal pictures will be made at the forthcoming surgical congress in Berlin.

BY order of Secretary Lamont, an examination into the physical condition of all army officers unfit for active service is being made. Those reported by the surgeon's certificate as permanently disqualified, may expect to be retired at once without reference to the usual age limit. It is said that this action was prompted by the small number of vacancies in the list and the want of places for the recent West Point graduates.

DR. PRIESTLEY has embodied in a report for the borough of Leicester, England, some interesting observations upon the earth's temperature and the prevalence of diarrheal diseases. Whenever the temperature of the earth, four feet below the surface, rises above 56° F., these intestinal affections become active, and the mortality tables for a fortnight later show them prominent among the causes of death. These results continue during the maintenance of this temperature and disappear after its subsidance.

ATTRACTED by the marked similarity, if not identity, of the bacillus of diphtheria and that found to exist in the nasal mucous membrane and its secretion in cases of ozena, certain Italian rhinologists have been led to try injections of the antitoxin in these heretofore intractable cases. The result in some thirty or forty patients has been quite unexpectedly gratifying. Of a series of thirty-two such cases, sixteen seemed radically cured, seven gave every promise of recovery, five were improved, and the remainder uncertain. The injection of ten cubic centimeters every day, or every second day, is usually followed by an immediate diminution in the odor and the amount of scabbing, while the secretion becomes more fluid and abundant. Duration of the treatment must vary with the exigencies of the individual case. Although it is entirely too early to regard such evidence as at all conclusive, especially when dealing with a disease so resistantly chronic, the theory underlying the experiment appears to be based upon a possible bacteriological relationship which would justify further investigation.

A NOVEL method of taking skiagraphs of the stomach is suggested by Dr. Hemmeter of Baltimore, in the last number of the *Boston Med. and Surg. Journal*. It was discovered by Rontgen, not only that metallic lead was quite opaque to the X-rays, but also the solution of its salts. The toxic effects of these prohibit their use as a means of distending the organ, but this objection is overcome by Dr. Hemmeter's proposition to first introduce a very thin and elastic rubber bag, which may afterward be filled with the solution and the picture taken.

A MACHINE has been invented by a Swedish engineer which will transform sterilized milk into butter in one

minute. Not only is time saved, but the butter is made absolutely pure and free from germs. The milk is heated in the sterilizer to 160° F. From the sterilizer it runs into a churning chamber, where it is cooled down to 60° in its progress, by means of very small cooling frames, through which iced water constantly passes, and which revolves with the churning chamber at the rate of six thousand revolutions a minute. Several advantages are claimed for this remarkable machine, which bids fair to create a revolution in butter-making upon a large scale. In the first place, by sterilizing the milk, disease germs, if they are in it, are destroyed, as well as the microbes which cause putrefaction of the butter. The process of buttermaking is so rapid that there is very little chance of any germs that may exist in the atmosphere of the dairy getting into the butter, especially as all, or nearly all, air must be forced out of the chamber of the machine by the extreme rapidity of the movement going on inside. When the butter is once pressed, the possibility of germ impregnation is almost eliminated. Thus, a wholesome and permanently pure butter is produced. Another advantage is that milk can be converted into butter directly after being obtained from the cow.

A verdict was given against a gold-cure in Boston last week. It seems that the proprietors quarreled. The one who had furnished the capital—$5000—wished to recover this amount because he claimed it had been fraudulently obtained. The member who was expected to furnish the experience had promised that the business should be successful and that at least a majority of the patients should be cured. It was abundantly proven that this part of the contract had not been kept, and hence the court sustained the claims of the party of the first part.

Dr. Roger S. Tracy, registrar of vital statistics, reports that for the week ended at noon, June 20th, there were 758 deaths in the city, of which 333 were cases of children under four years.

CORRESPONDENCE.

To the Editor of The Medical News.

Dear Sir: In the *Journal of the American Medical Association* there is a paragraph, "A Recruit for Achilles Rose," telling that Dr. Loeffler of Dresden, Germany, writes his prescriptions in Greek characters. With all due respect for Dr. Loeffler, one of the prominent German physicians, I wish to say that he is like some Catholics, who are more Catholic than the Pope. The Greeks themselves write their prescriptions as the physicians of other countries do, in Latin, with Latin characters, only the directions are, as a matter of course, written in Greek. Dr. Loeffler's idea, however, is an excellent one, and we might write our ordinations in Greek for the same reason for which the Greeks write them in Latin, namely, that the public should not read them.

Yours,

A. Rose.

New York,
June 16th.

REVIEWS.

Manual of Medical Jurisprudence and Toxicology. By Henry C. Chapman, M.D., Professor Institutes of Medicine and Medical Jurisprudence, Jefferson Medical College. Second edition, 254 pages, 35 illustrations, 3 colored plates. Philadelphia: W. B. Saunders, Publisher.

In many respects this volume of about 250 pages constitutes a most valuable addition to the working library of the general practitioner. It is essentially and very desirably practical, containing an abundance of material gathered from the everyday experience of one who is thoroughly familiar with most of his subject. Unfortunately, the author has overstepped in one sub-field the domain of personal knowledge, the chapter upon insanity, in its medico-legal aspects, indicating a most pitiable lack of information. Insanities, for example, are classified under three groups: amentia, mania, and dementia. Paranoia is not recognized, nor is the word mentioned, while melancholia the author describes as "a variety of mania." The paragraph upon homicidal mania is dangerously misleading in several statements, in that the author leaves the inference that homicidal impulses are found in one variety of insanity only, that there is characteristically entire absence of motive, and that no effort is made in such cases to escape detection or punishment. As this chapter was present in the first edition, it is difficult to conceive how it ever appeared in a second edition unchanged, a fact to be especially regretted, as it seriously mars an otherwise exceedingly creditable work.

An Introduction to Pathology and Morbid Anatomy. By T. Henry Green, M.D., F.R.C.P. Seventh American from the Eighth English Edition. Revised and enlarged by H. Montague Murray, M.D., F.R.C.P. Illustrated by 224 engravings. Philadelphia: Lea Brothers & Co., 1895.

The most active workers in the whole domain of medical science are unquestionably the pathologists. Through their unflagging zeal discoveries are added to discoveries with such great rapidity that even the most advanced textbooks are antiquated before they have reached the age of a lustrum.

No one could deny that the previous edition of Green's Pathology, though fully abreast of the progress in its subject at the time of publication, was no longer adequate to the needs of the student.

It is, therefore, meritorious on the part of the editor and the publishers to bring out another edition. The present one—which is the seventh American from the eighth English edition—has been carefully revised by H. Montague Murray, and takes account of nearly all the important advances in pathologic science. To select only one or two subjects we find for example, that the etiology of carcinoma is discussed with conciseness and impartiality, the editor very properly concluding that the parasitic nature of the cell-inclosures must still be considered as being *sub judice*. The chapter on diseases of the nervous sys-

tem is good, and the illustrations in it are well chosen. The article on inflammation has not been greatly modified, and reference to the rather important subject of chemotaxis is omitted. The infectious granulomata are treated with thoroughness, both from the bacteriologic and the anatomic standpoint. The editor has succeeded admirably in preserving the clearness of diction for which Green's Pathology has always been noted, and which makes the reading of the book so pleasant.

SYPHILIS IN THE MIDDLE AGES AND MODERN TIMES, being Vols. II and III of "Syphilis To-day and Among the Ancients." By DR. BURET, Paris. Translated from the French by A. H. Ohmann-Dumesnil, M.D.

Vol. II, "Syphilis in the Middle Ages," a historical sketch, essays to expound, by "scientific documents" and "historical and literary documents," in chapters 1 and 2 the pre-Columbian existence of syphilis. This the author accomplishes by narrating a string of indecent excerpts relating to the licentiousness of this era. He considers this stirring up of much filth "indispensable."

The remaining chapters of this volume discuss the relation of syphilis to the various epidemics, notably the epidemic of Naples, and are devoted to the same purpose—that of establishing the medieval existence of syphilis and of disproving its American origin.

Vol. III, "Syphilis in Modern Times," traces the history of syphilis and the growth in its treatment from the Middle Ages down to the present time.

The general tone of this work, whether intended so or not, is distinctly sensational.

VOICE BUILDING AND TONE PLACING. By H. HOLBROOK CURTIS, M.D. D. Appleton & Co., New York.

THE most interesting part of this book, from a medical standpoint, is found in chapters VI and VII, the origin of certain diseased conditions of the vocal cords produced by improper use of the voice, "Nodules of Attrition," alias "Corns of the Vocal Cords," alias "*Betes Noires* of Artists." The author gives slight attention to the pathology or nature of these, but devotes some space to their etiology.

The etiology is based upon the supposition that the vocal cords while vibrating act like reeds. Much energy and space is devoted to prove that they act in this manner, and many diagrams are given to illustrate the motion of the cords while vibrating, and the author goes into a detailed description of the stroboscope, by means of which he has seen the cords do all these things. Now, if the vibrating cord is segmented after the manner of reeds, we will have the same arrangement of partial tones in the voice that we have in the reed; because it is the segmentation of the cord while vibrating that gives partial tones. By means of properly tuned resonators one is able to pick out the partial tones of the voice, or any other musical sound. The first overtone of the voice is the octave produced by the cord vibrating in two equal segments. The second overtone, the fifth of the first octave produced by three equal vibrating segments. The third overtone, the octave produced by four segments. The fourth overtone, the third of the second octave produced by five segments. The fifth overtone, the fifth of the second octave produced by six segments. The sixth overtone, the minor seventh of the second octave produced by seven segments, and the seventh overtone the third octave, produced by eight segments. Now the overtones of a reed do not lie in this series. The first overtone of a reed lies between the sixth and seventh partial tones of the voice; hence we have five overtones in the voice before we come to the first overtone of the reed. These five overtones are the most important in determining the quality of the voice. Recent investigations have demonstrated that when the lower partial tones are weak, we get the disagreeable quality of twang which is known as "reedy"; if we examine the overtone of a string, we find that it has precisely the same relation to the fundamental that the overtones of the voice do, and we are forced to conclude that the vibrating cord acts like a string and not like a reed. Again, we find the same factors brought into use in raising the pitch in both the cord and the string *i.e.*, length, weight, and degree of tension. By the proper mechanism we can change the length, weight, and amount of tension of the vibrating cord, just as we find different lengths, weights, and degrees of tension in stringed instruments. The conditions which determine the pitch of the reed are length, weight, and rigidity (elasticity). The cord, like the string, is attached at both ends, and is thus capable of being subjected to different degrees of tension, while the reed is free at one end, and tension has nothing to do with its pitch.

On page 144, Fig. 38, Dr. Curtis gives us an illustration of the first stage in the development of these "nodules." Anyone who has ever seen the vocal cords in action, or who understands the anatomy of the larynx, would know that this is an impossible position of the cords. There is no possible means of getting a separation of the anterior attachments of the cords while they are approximated in the middle. As the reed theory, on which the author depended to substantiate this position (see p. 124), has been exploded, there is nothing left to fall back upon. Figs. 39 and 40 can only be interpreted as examples of tumors of the vocal cords, which nothing but surgical interference could remove.

It is ridiculous to suppose, in the first place, that anything resembling the structure of a corn could form on the vocal cords, and in the second place, if it had been formed, it would be impossible to remove it in a few hours, or a few days even, as the author claims to do by simple tone exercises. Fig. 41 is an impossible position of the cords, as their front attachments are separated. Fig. 42 shows a paresis of the intrinsic muscles.

Chapter VI is a very troublesome one. It contains among other things the author's theory of registers, which, to say the least, is peculiar. On page 132 there is a diagram to illustrate that there is no segmentation of the cord in the chest register. On page 133 diagrams illustrating the segmentation of the cords in the head register. The truth is that there is far more segmentation of the cord in the lower than the higher tones. The higher the pitch the fewer partial tones, and these partial tones are dependent on segmentation of the cord. On page 134

we read "The vocal cord is thus divided into two unequal segments." This never happens, as the relations of our partial tones would then be disturbed, but they are always the same. Space forbids a detailed criticism of his treatment of registers. Suffice it to say that with the proper mechanism all the changes necessary to produce any pitch are brought about by the simultaneous action of the muscles: the crico-thyroid, which gives the degree of tension required and the thyro-aritenoideus which produces the shortening and the lessening of the weight of the vibrating cord. These muscles act through the whole range of the voice, therefore there is no change in mechanism and no registers. Registers only occur in bad productions.

On page 116 occurs the passage, "The tones are not always the result of the vibration of the cords themselves, but of the vibration of air columns in the vocal tube and resonating cavities." This is an impossibility, as the vocal cords originate all the vibrations. These resonance cavities can only reinforce or eliminate certain partial tones, and it is the use of the resonance cavities in this way which enables us to articulate. The vocal cords originate the same series of vowels, and the size and shape of the resonance cavities determine which series of waves shall be reinforced, and which shall be suppressed, thus determining the vowel sound. This same error is made on page 83 in regard to the sounding boards of instruments. Sounding boards only reinforce, they do not originate tone.

Chapter III is devoted to breathing. The author decides that the high chest position, combined with inferior cortal breathing, is the correct thing. He bases this decision on the supposition that the high chest position gives a large amount of chest resonance, thereby adding greatly to the carrying power and strength of the tone. We believe that the essential feature of the resonator is a free communication with the external air. The chest, while a tone is being produced, is a closed cavity, therefore it cannot act as a resonator to reinforce the tone, and chest resonance is absurd. It is true that the air in the chest vibrates, but these vibrations cannot get out to create a disturbance in the external air. The only cavities which can reinforce tone are the pharynx, nose, and mouth. The author states, page 73, that the antra, and sphenoidal and frontal sinusus are important resonance cavities. This is not true, as they are practically closed cavities, as far as free communication with the external air is concerned.

Chapter II, treats of the anatomy and physiology of the larynx. On page 42 is found "The strength of the expiratory blast effects the pitch of the tone." This is not true, as the strength of the blast determines the intensity of the tone only. On page 95, is this statement. "A simple fundamental tone is not known in music," on page 88, "In an organ each pipe is constructed so as to give only its fundamental note" (tone). On page 95, the author speaks of "undertones" phenomena unknown to authorities in physics. On page 96, "The fact that the fundamental tone sets the air into secondary vibrations can be shown." The fundamental as well as the overtones are produced by the vibrator. One set of air waves cannot originate another set. On page 101, "The same conditions for the production of overtones exist in the reed as in string instruments." We have just shown that the same conditions do not exist, and that their overtones are very different. The first overtone of the reed is between the fifth and the sixth of the string. The second, between the sixth and seventh of the string. The third, between the thirty-third and thirty-fourth of the string, and the fourth, between the fifty-fifth and fifty-sixth of the string. On page 144, he refers to the "longitudinal vibrations of the vocal cords," a physical impossibility. On page 155, "After the experience with the correct focus of tone, etc." When we consider that the sound waves of C2 are about nine feet long, and C5, its seventh overtone, about one foot long, it is a little difficult to see how these waves, which are originated by the vocal cords, can be focused "dans le masque." On the same page, "These are the experiences, so much appreciated by singers, that we employ for the reduction of nodules of attrition on the cords, which exercises, strange to say, have been the subject of ridicule by certain laryngologists, who have undoubtedly not given the subject of physics a proper amount of consideration."

We have seen that the "nodules" are a myth, or at least nothing more serious than collections of mucus, which are readily thrown off by vibration of the cords. On page 55, "We are indebted to the stroboscope for the scientific vindications of our theory and treatment of singers' nodules." The stroboscope, instead of vindicating his theory of nodules, has led him sadly astray. Finally, Chapter IX, is devoted to voice figures. These diagrams simply illustrate the vibration of plates and membranes, and have nothing whatever to do with the voice.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 26, 1896, TO JUNE 1, 1896.

Leave of absence for four months on surgeon's certificate of disability, is granted to First Lieutenant Benjamin Brooke, assistant surgeon.

The order assigning Captain Ashton B. Heyl, assistant surgeon, to duty at Fort Canby, Washington, is revoked; he is relieved from duty at Fort Thomas, Kentucky, and ordered to Fort Riley, Kansas, for duty, relieving Captain Thomas V. Raymond, assistant surgeon. Captain Raymond, on being thus relieved, is ordered to Fort Canby, Washington, for duty,

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE SIXTEEN DAYS ENDED MAY 31, 1896.

Hamilton, J. B., surgeon, granted leave of absence for ten days, May 23, 1896.

Brown, B. W., passed assistant surgeon, granted leave of absence for six days, May 25, 1896.

Gardner, C. H., assistant surgeon, ordered to examination for promotion, May 27, 1896.

BOARDS CONVENED.

Board convened to meet in Washington, D. C., June 15, 1896, for the examination of officers for promotion and candidates for appointment in service. Surgeon G. W. Stoner, chairman; Surgeon Fairfax Irwin, Passed Assistant Surgeon C. E. Banks, recorder, May 25, 1896.

INDEX.

ABDOMEN, opening of, in middle line, 46
Abdominal ailments, operative interference in, 559
wall, extensive laceration of, 14
Abortion of gonorrhea, 571
Abscess, pneumococcus, 242
in mastoid region associated with diabetes mellitus, 324
of the spinal cord, 541
of brain, 42
subdiaphragmatic, 593
Absorption in the stomach, 596
Acetanilid in chronic suppurative otitis, 377
Actinomycosis, 596
Action of erysipelas on syphilis, 409
of the stomach, mechanical causes of interference with, 560
Acromegaly complicated by posterior sclerosis, 209
Acute appendicitis, 269
ascending paralysis, a contribution to the study of, 333
mastoiditis with diabetes mellitus, 494
Addison's disease, experimental, 295
pathology of, 703
Address, Cole, R. B., 505
on medicine, Osler, W., 506
on State medicine, Rohe, G. H., 510
on surgery, Senn, N., 507
Adenoid vegetations of nasopharynx, 75
Advances in therapeutic during the year, 536
Advertise? Which does it, 20
Aeroporotomy, 650
Affection of the upper respiratory tract, recent progress of treatment in, 250
Albuminuria from vaccination, 354
Alcohol, effects on organs of special sense, 597
Alcoholic cirrhosis of the liver, 646
Alcoholism and public health, 160
Alexander's operation, indications for, 281
Amateur surgery, 355
Ambulatory treatment of Pott's disease, 231
American Academy of Medicine and Medical Teaching, 439
Gynecological Society, 647
Anders, J. M., typhoid fever as a complication and sequel of influenza, 337
Anemia, pernicious and other forms of, 591
Animal life without bacteria in the alimentary canal, 109
Anterior ventral fixation after removal of a subperitoneal pedunculated myoma, 278
Antiphthisin, 199
Anti-streptococcus serum in scarlatina, 726
Anthrax in rabbits treated by intravenous injections of nucleinic acid, 541
Antiseptic action of subnitrate of bismuth, 616
Antitoxin by electrolysis, 541
Dr. Winter's observations on, 691
in the treatment of diphtheria, 213, 537
in diphtheria, 646
treatment of diphtheria, 727
treatment, 471
in treatment of tetanus, 46
treatment of recent diphtheria epidemic in Chicago, 216
Antivivisection, 243
bill in congress, 188–193
of Massachusetts, 303
An unusual vibratory cicatrix in the membrana tympani, 724
Anurism of the thoracic aorta, 205
Aphasia, medico-legal aspect of, 16
from subcortical hemorrhage, 698
congenital, 18
Aphemia, 18
Appendiceal abscess, 127
Appendicitis, early operation in, 515
Appendix vermiform, technic of removing, 565.
A resume of ten months of vaginal work, 719
Argonin, 410
Army, U. S., vacancies in, 712
Artificial eye, sponge grafting in the orbit for support of, 721
leukocytosis in the treatment of septic processes, 726
Articular rheumatism, serum in, 702
Ascending degeneration of the pyramidal tracts, 209
Asexualization in the prevention of crime, 573.
Association of American Physicians. Our professional "Immortals," 525
A study of sporadic cretinism, 332
Atlanta meeting of the American Medical Association, 497
Attendance at medical societies, 475

BACTERIA, 526
Bacteriological Department of Philadelphia Board of Health, 551
Bacteriology of empyema in children, 164
Bangs, L. B., calculi of the prostate, 657
Barbour, L. P., antiphthisin, 199
Barclay, R., foreign bodies in the ear, 45
Barham, C. R., toxic erythema, 351
Baruch, S., hydrotherapy in typhoid fever, 463
Beauty as an aim in medicine, 273
Belladonna poisoning, 101
Bellevue Hospital, evolution of, 703
Belt, E. O., consanguineous marriage, 61
sponge grafting in the orbit for support of artificial eye, 721
Benedict, A. L., hydrotherapy in typhoid fever, 141
Bierwirth, J. C., clinical aspect of chronic diffuse nephritis, 367
Bile passages, surgery of, 612
Bipolar stomach electrode (intragastric), 240
Bishop, L. F., diagnosis and treatment of gout, 64
Blepharoplasty, 41
Blood and the salts of lime, 128
serum of vaccinated heifers, 354
Bone marrow, glycerin extract of, 303
Bradley, A. E., nerve-grafting, 153
urethral hemorrhage, 15
Brain, tumor, specimens of, 136
injuries and operations upon, 558
tumors, 162
Braid treatment of typhoid fever, 578
Brannan, J. W., Analysis of Dr. Winters' observations on antitoxin, 691
Bright's disease, 608
Brinton, D. G., degenerations of the female reproductive organs, 68
Bromic intoxication, 592
Broncho-pneumonia in the newborn, 72
in children, 272
Bronchitis, idiopathic fibrinous, 645
Brooklyn Jennerian centennial, 617
Bulletins of the New York Board of Health, 362
Burns, 410

CÆSAREAN section, 601, 666
post-mortem, 75, 119
technic of, 161
Calomel as a specific in diphtheria, 465
Campbell, J. T., pharyngomycosis leptothrica, 371
Cancer cure institutions, so-called, 160, 174
Cancer of nose, 103
Cancer of the uterus, complicated by pregnancy, 472
Capillary holes in the skull, exploration of brain through, 566
Carcinoma of the breast, 269
of the lip and jaw, 321
of the cervix uteri, rational treatment of, 530
of the rectum in a youth, 616
Carcinomata in the same individual, two primary, 155
Cardiac disease in the quiescent period, 598
Care act, the State, 157
Carr, W. P., mammary neoplasms, treatment of, 29
Cases illustrating various pathological stages in inflammatory pelvic disease, 238
Castration, double, for hypertrophy of prostate, 91
immediate results produced by, 46
Cataract, urology of, 725
Cates, B. B., fractures of bones of the elbow-joint, 716
Cattell, Henry W., Röntgen's discovery, 169
Cauthorn, F., acute strangulated hernia, 95
Celiotomy in the newborn, 665
in a case of obstinate dysentery, 155
Celluloid to cover defects in the skull, 162
Cerebral surgery, 75
recent progress in, 440
traumatism and dypsomania, 381
Cervix uteri, rational treatment of carcinoma of, 530
Chancre of the tonsil and tongue, 519
Cheney, W. F., scurvy in infants, 227
Chilblains, treatment of, 242
Chloroform, death under, 18
Cholelithiasis and cholelithotomy, 559
Chorea, 364
Chronic diffuse nephritis, clinical aspect of, 387
Chronic neurasthenia, special education as a means of treatment in, 472
Circumcision not necessary in young children, 600
Clinical aspects of glycosuria, 445
aspect of chronic diffuse nephritis, 387
Clot, subdural, 41
Coakley, C. G., statistics of diphtheria, 697
Cocain poisoning, 203
Code of ethics, 475
Coe, H. C., Cæsarean section, 601
Cold baths a heart stimulant, 248
Cole, R. B., address, 505
